Working Draft Document

1 The National Park Service, Natural Resource Stewardship and Science office in Fort Collins,
2 Colorado, publishes a range of reports that address natural resource topics. These reports are of
3 interest and applicability to a broad audience in the National Park Service and others in natural
4 resource management, including scientists, conservation and environmental constituencies, and the
5 public.

6 The Natural Resource Report Series is used to disseminate comprehensive information and analysis
7 about natural resources and related topics concerning lands managed by the National Park Service.
8 The series supports the advancement of science, informed decision-making, and the achievement of
9 the National Park Service mission. The series also provides a forum for presenting more lengthy
10 results that may not be accepted by publications with page limitations.

11 All manuscripts in the series receive the appropriate level of peer review to ensure that the
12 information is scientifically credible, technically accurate, appropriately written for the intended
13 audience, and designed and published in a professional manner.

14 You must add a peer review statement here that has been approved by the Peer Review Manager of
15 the report.

16 Views, statements, findings, conclusions, recommendations, and data in this report do not necessarily
17 reflect views and policies of the National Park Service, US Department of the Interior. Mention of
18 trade names or commercial products does not constitute endorsement or recommendation for use by
19 the US government.

20 This report is available in digital format from Your_Office_Name website (<http://...>), and the Natural
21 Resource Publications Management website (<http://www.nature.nps.gov/publications/nrpm/>). To
22 receive this report in a format optimized for screen readers, please email irma@nps.gov.

23 Please cite this publication as:

1 **Executive Summary**

2 In October 2012, a breach was formed in the National Park Service (NPS) Otis Pike Fire Island High
3 Dune Wilderness as a result of storm effects from Hurricane Sandy. The NPS is preparing an
4 environmental impact statement (EIS) to evaluate alternatives for managing the breach. Because the
5 breach had existed for less than three years at the initiation of the EIS project, much of the research
6 relating to the breach was or is still underway. To support the development of the EIS, existing and
7 ongoing research pertaining to the pre-breach and post-breach conditions in Great South Bay and
8 surrounding areas was collected, compiled, and synthesized into this technical synthesis report. This
9 report is a compilation of the best available information and describes the current state of the science
10 for the physical and natural resource issues specific to Great South Bay and surrounding areas, as
11 identified by NPS.

12 This technical synthesis report presents a synthesis and summary of published and unpublished
13 studies, and information gained from discussions with subject matter experts. The report is divided
14 into two main resource areas: (1) a physical resources section, and (2) a marine and estuarine
15 resources section. The physical resources section summarizes information regarding hydrodynamic
16 processes, water quality properties, waves, sediment transport, breach geomorphology, and long-term
17 issues such as climate change and sea level rise. The marine and estuarine resources section provides
18 a summary of information on water quality and phytoplankton, wetlands, submerged aquatic
19 vegetation (SAV), benthic communities, hard clams, finfish and decapods, and ecosystem structure
20 and processes. The resource areas covered under each chapter were identified as the resource areas
21 most likely to experience and elicit responses to potential breach-related conditions. The information
22 contained in this synthesis report will provide the scientific foundation for the EIS.

23 Effects of the breach on high tide water levels in Great South Bay from daily tidal fluctuations and
24 small surge events were evaluated through the use of hydrodynamic modeling and analyses of tide
25 gage data. Both modeled and measured data indicate that high tide water levels follow a gradient,
26 with small increases in water levels in the western and central parts of Great South Bay and minimal
27 changes in the eastern parts of the bay. The greatest change in high tide water levels was observed
28 near Lindenhurst, in western Great South Bay, where modeling and tide gage data indicate elevations
29 have increased between 2.0 and 2.5 centimeters (0.8 and 1.0 inches) since the breach occurred.
30 Elsewhere in central and eastern Great South Bay, modeling and measured data show that high tide
31 water level increases have been very small at less than 0.8 centimeters (0.3 inches).

32 Stage frequency curves generated from numerical modeling of pre and post-breach conditions
33 indicated a maximum water level increase likely under the 100-year return period scenario (1%
34 annual chance) of 60 centimeters (24 inches) for the Connetquot River area of the central Great
35 South Bay. Under the same 100-year return period scenario, stage frequency curve data exhibited
36 increases of 20 to 40 centimeters (7.9 to 15.7 inches) in other areas of Great South Bay and Moriches
37 Bay. The stage frequency curves, originally based on model simulations with a breach nearly
38 2.5 times larger than the current opening, were adjusted using model runs on a breach configuration
39 measured in June 2014. The 100-year return period water levels are predictions based on statistical

1 analyses of numerical model simulations of a dynamic coastal system. While absolute values of
2 storm related water levels are difficult to predict, the order of magnitude and spatial distribution of
3 the modeled increases is considered reliable.

4 Geomorphic impacts due to waves and sediment transport as a result of the breach are localized to a
5 zone approximately 0.5 to 1.0 kilometer (0.3 to 0.6 mile) from the opening, primarily on the ocean
6 facing western or down-drift side of the breach. Shoreline change data suggest that the breach causes
7 little interruption in longshore sediment transport processes, although studies regarding directions of
8 sand transport through the breach have not been conducted and model results regarding ebb/flood
9 dominance are contradictory.

10 Wave conditions inside Great South Bay have not been impacted by formation of the breach as the
11 limited width of the breach and the shallow nature of the flood tidal delta complex do not allow wave
12 propagation from the ocean through to Great South Bay. The cross-sectional area of the breach
13 increased during the first two years after formation, with only small variations in width occurring
14 beyond the two-year time frame. Following initial formation, the main channel of the breach
15 migrated gradually to the west. It is expected that the extent of westward migration will be limited by
16 the location of erosion resistant geologic deposits located approximately 1.5 kilometers (0.9 miles)
17 west of the May 2015 breach centerline. Further, the breach resulted in a change in general
18 circulation patterns in eastern Great South Bay from stationary eddies to a pattern of mean through-
19 flow moving from east to west. This shift in general circulation patterns has resulted in a decrease in
20 water residence times for Great South Bay as a whole, and Bellport Bay in particular.

21 Water quality in Great South Bay has improved since formation of the breach. Salinities have
22 increased between 2 and 5 practical salinity units (psu) in the central and eastern parts of the bay.
23 Water temperature in the summer has decreased by 3°C, dissolved nitrogen has decreased by
24 0.2 milligrams per liter (mg per L), water clarity has improved, and chlorophyll-a concentrations
25 have decreased from a range of 18 to 42 micrograms per liter (µg per L) prior to the breach, to a
26 range of 6 to 15 µg per L in 2014, and a range of 26 to 35 µg per L in 2015. The frequency and
27 intensity of brown tide has decreased in areas of eastern Great South Bay where water quality has
28 improved and following bloom events, brown tide cells are cleared from the bay more quickly by
29 transport to the ocean through the breach. Species composition of phytoplankton shifted after the
30 breach occurred, and now is dominated by chain-forming diatoms with larger cell sizes. Central
31 Great South Bay has experienced increased brown tide bloom frequency and intensity since the
32 breach formed, potentially a result of changes observed in general water circulation patterns in Great
33 South Bay.

34 Coastal habitat availability for Great South Bay fauna has changed since the formation of the breach.
35 Field surveys indicate that beds of eelgrass have become established east of the breach in response to
36 improvements in water quality, and new sand platforms have formed in the flood tide delta as a result
37 of the accumulation of sandy sediment in overwash areas. The newly formed sand platforms provide
38 opportunities for future establishment of marsh habitats, the type typically dominated by the marsh
39 plant *Spartina alterniflora*. The potential for colonization by marsh plants would be more favorable if
40 the flood tide delta becomes less dynamic (i.e., less shifting sediment). The post-breach

1 improvements observed in water quality could further encourage marsh and seagrass bed
2 development. Coastal vegetation is important for nutrient and carbon cycles, food resources for fish
3 and waterfowl, nursery habitat and refuge space for juvenile fish, sediment stabilization, and water
4 quality; benefits provided by sequestering nutrients and trapping suspended sediments and organic
5 matter.

6 Changes in the faunal community of Great South Bay have also been observed since the breach
7 formed, particularly in Bellport Bay, Narrow Bay, and western Moriches Bay, where water quality
8 has improved. Post-breach surveys indicate that total abundance and diversity of finfish species has
9 generally increased. The observed changes are attributed to a response to improvements in water
10 quality, moderated summer and winter water temperatures, and increased habitat availability (i.e.,
11 increased SAV density and eelgrass). However, declines observed for some species, such as blue
12 crab (*Callinectes sapidus*), are a potential result of increased salinities; while declines observed for
13 grass shrimp (*Palaemonetes vulgaris*) were attributed to increased predation by fish foraging in
14 seagrass habitats near the breach. Hard clam growth rate and condition index have both improved in
15 Bellport Bay in response to post-breach improvements in water quality and food quality, and the
16 ameliorating effect that the breach has had on brown tide blooms there. However, in central Great
17 South Bay the post-breach circulation patterns create conditions that favor brown tide blooms and
18 have negatively affected hard clams.

19 Post-breach changes in the benthic community are likely to have occurred, but have not yet been
20 studied. Benthic communities are sensitive to sediment grain size and water quality. Overwash and
21 development of flood shoals consisting predominantly of sand have likely increased the sediment
22 grain size in the vicinity of the breach. The environmental conditions resulting from the breach favor
23 high-flow, high-salinity adapted benthic communities comparable to those observed in the vicinity of
24 other Great South Bay inlets.

25 Prior to breach formation, the Great South Bay was characterized as an immature ecosystem with
26 lower connectivity to the ocean, thus limiting the health and stability of the bay system. The post-
27 breach changes documented in the Great South Bay and resulting from increased ocean connectivity
28 include improvements in water quality, temperature moderation, increased species richness, and
29 abundance, and formation of new aquatic habitats, including eelgrass beds. Further, marsh grass is
30 more abundant and could potentially colonize overwash areas and the flood tide delta, which would
31 support increased fish and invertebrate production. Other metrics of ecosystem maturity, such as food
32 web complexity and the abundance of suspension feeders and upper trophic levels have not been
33 evaluated post-breach and are not known at this time, but may have also been affected by the breach.
34 As a result of the post- breach changes in the Great South Bay, the ecosystem is more characteristic
35 of a mature ecosystem, exhibiting increased species richness and abundance, and more desirable
36 characteristics such as improved system health, stability, and resilience to disturbance.

1 Introduction

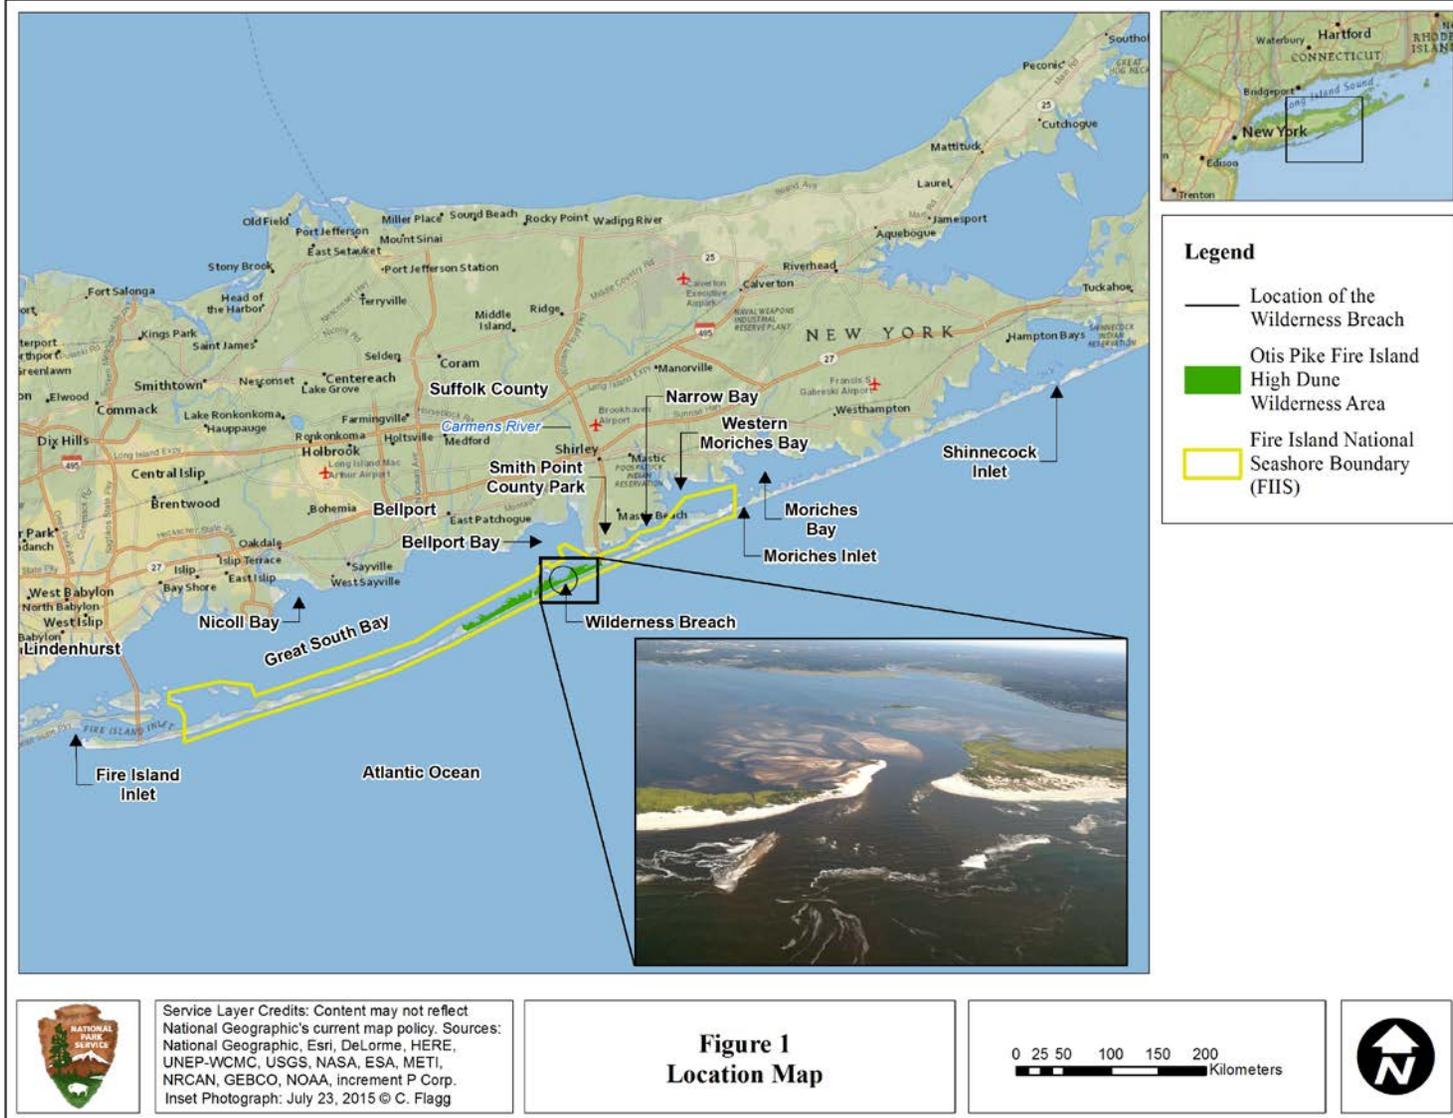

2 In October 2012, Hurricane Sandy made landfall in the United States near Brigantine, New Jersey.
3 The storm caused wave and flood related damages in New Jersey and New York, and formed a
4 breach in the National Park Service (NPS) Otis Pike Fire Island High Dune Wilderness located on
5 Long Island (Figure 1). The existing Breach Contingency Plan (USACE 1996) guides the response
6 for breaches that form along Fire Island, with breach closure typically occurring immediately after
7 the formation of the breach; however, the Breach Contingency Plan provides an exception for
8 breaches that form in the wilderness. These breaches are to be studied to determine if natural closure
9 will occur. Federal wilderness areas are wild, undeveloped federal lands that have been designated
10 and protected by congress. The legislation creating the wilderness area (Public Law 96-585) directs
11 the Seashore to manage this area to preserve the wilderness character. The legislation also directs the
12 NPS to refrain from interfering with natural processes that would typically occur within a barrier
13 island, including breaches. The legislation does not preclude closing a breach in the wilderness if
14 there is a need to do so; however, the *Fire Island National Seashore Wilderness Management Plan*
15 (NPS 1983) stipulates that an environmental impact statement (EIS) must be prepared and public
16 review and comment on alternatives must be conducted before such a decision would be made. For
17 this reason, the NPS is preparing an EIS to evaluate alternatives for managing the breach.

18 As a result of the breach, numerous studies were initiated by researchers to better understand the
19 dynamics of the breach and the effects of the breach on various elements of the Great South Bay
20 ecosystem. As noted above, breaches along Fire Island are typically closed immediately, so this
21 offered researchers a rare opportunity to study the dynamics of the breach following its formation
22 and the effects of the open breach on the bay ecosystem. Much of the research relating to the breach
23 is still underway. In order to access the most current scientific information and to reach consensus
24 among researchers on resource issues, NPS elected to prepare this technical synthesis report to
25 compile and document the best available data and describe the current state of the science for the
26 physical and natural resource issues, as identified by NPS. This information will provide the
27 scientific foundation for the EIS.

28 To collect the information needed for this technical synthesis report, NPS researchers and consultants
29 developed a program designed to collaborate with subject matter experts (SMEs) and document
30 ongoing research. SMEs consisted of university professors, student scientists, and postdoctoral
31 researchers; federal and state agency staff, listed in Table 1. The program consisted of initial data
32 requests, review of available information provided by SMEs and obtained from the literature, and a
33 workshop to process and discuss the information obtained, all leading to the development of this
34 report.

35 In January 2016, NPS hosted the workshop, bringing together the SMEs and providing an
36 opportunity for the SMEs to discuss the current science in the context of the issues that would
37 potentially drive the EIS decision. Results from discussions were compiled into daily meeting
38 summaries, which were used in the development of the draft technical synthesis report. The final

- 1 draft provides the technical details on the current state of the science for physical and ecological
- 2 resources related to the breach, and, as noted above, provides the scientific foundation for the EIS.

3

1 **Physical Resources**

2 Physical processes in the vicinity of the Fire Island wilderness breach and Great South Bay play an
3 important role in defining impacts of the breach on the ecological resources, the surrounding natural
4 and developed lands, and the communities that inhabit the south shore of Long Island. Prior to
5 Hurricane Sandy, open ocean and inlet dominated physical processes were active along the barrier
6 beach and at the two tidal inlets, Fire Island and Moriches. Storm generated overwash processes were
7 active along the lower more vulnerable areas of the barrier. Conditions within Great South Bay were
8 controlled primarily by estuarine processes, with tidal exchange controlled by the two established
9 inlets located approximately 50 kilometers (31 miles) apart (Figure 1). With formation of the Fire
10 Island wilderness breach, a dynamic new environment was formed that increased the connectivity
11 between Great South Bay, western Moriches Bay, and the Atlantic Ocean, allowing greater influence
12 to the bays from ocean and inlet processes.

13 The breach has resulted in changes to physical factors that affect the barrier beach, nearby shoals,
14 and the Great South Bay estuary. The primary physical factors include hydrodynamics, water quality
15 properties, waves, sediment transport, and island geomorphology. Superimposed on the short-term
16 changes to the system caused by the breach are the longer-term impacts caused by climate change
17 and sea level rise. The information presented in this technical synthesis report addresses the current
18 scientific knowledge regarding changes to these physical factors as a result of the breach, as well as
19 impacts to Great South Bay and the surrounding areas.

20

1 **Hydrodynamics**

2 Changes in the hydrodynamics of Great South Bay and Moriches Bay as a result of breach formation
3 have the potential to affect water levels in the bays. This includes daily changes in water levels
4 caused by astronomical tides as well as storm-generated water levels. The tidal prism of the breach,
5 or the volume of water exchanged during a tidal cycle excluding any contributions from freshwater
6 inflows, is an important component of the hydrodynamics that can also influence bay water levels.
7 Prior to formation of the breach, the hydrodynamics and water levels were controlled primarily by
8 water exchange through Fire Island and Moriches Inlets. However, with the addition of the Fire
9 Island wilderness breach, there is potential for alteration to these processes. General circulation
10 patterns in the bays may also be affected, and this in turn can influence basic water quality
11 parameters such as salinity, water temperature, water clarity, and nutrient concentration.

12 **Synthesis of Hydrodynamics Pre- versus Post-Breach**

13 Effects of the breach on hydrodynamics have been studied by three primary groups: the US Army
14 Corps of Engineers (USACE), US Geological Survey (USGS) in cooperation with Deltares, and the
15 State University of New York (SUNY) Stony Brook University. While the goals of the three studies
16 were different, they each provide valuable information on changes to the hydrodynamics of the bays
17 along the south shore of Long Island (Great South Bay, Moriches Bay, Shinnecock Bay) as a result
18 of the breach. A brief summary of each study is provided below followed by a summary of findings
19 and conclusions regarding impacts of the breach on water levels and circulation in the bays.

20 ***US Army Corps of Engineers Model Studies***

21 Numerical modeling of physical processes for the south shore of Long Island was undertaken by the
22 USACE New York District in support of the Fire Island Inlet to Montauk Point Reformulation Study
23 (FIMP). The purpose of the modeling was to determine storm impacts and bay flood levels along the
24 south shore of Long Island between Fire Island Inlet and Montauk Point to inform decisions on long-
25 term management of the FIMP area for storm damage reduction. Information on initial modeling
26 conducted for FIMP is contained in a draft report entitled *Baseline Conditions Storm Surge Modeling*
27 *and Stage Frequency Generation: Fire Island to Montauk Point Reformulation Study* (USACE
28 2006a). The work is also summarized by Canizares and Irish (2008), the primary modelers.

29 The modeling approach for FIMP incorporated a wide array of physical processes including winds,
30 barometric pressure, astronomic tides, waves, morphologic response, and localized wind and wave
31 setup. Specialized numerical models capable of simulating hydrodynamics, waves, and sediment
32 transport were merged and used to evaluate surge elevations in Great South Bay and surrounding
33 areas under a range of storm and breach scenarios. The modeling approach used the following four
34 process models:

- 35 • WAVAD (i.e., WISWAVE) to determine extreme storm wave conditions,
- 36 • ADvanced CIRCulation model (ADCIRC) to simulate storm water levels in the ocean,
37 nearshore, and areas seaward of the surf zone,

- 1 • Storm-induced BEAch CHange model (SBEACH) to estimate pre-inundation dune lowering,
2 and
- 3 • Delft3D model suite to simulate storm water levels in the bay accounting for contributions
4 from storm surge, waves, winds, overwash, and/or breaching.

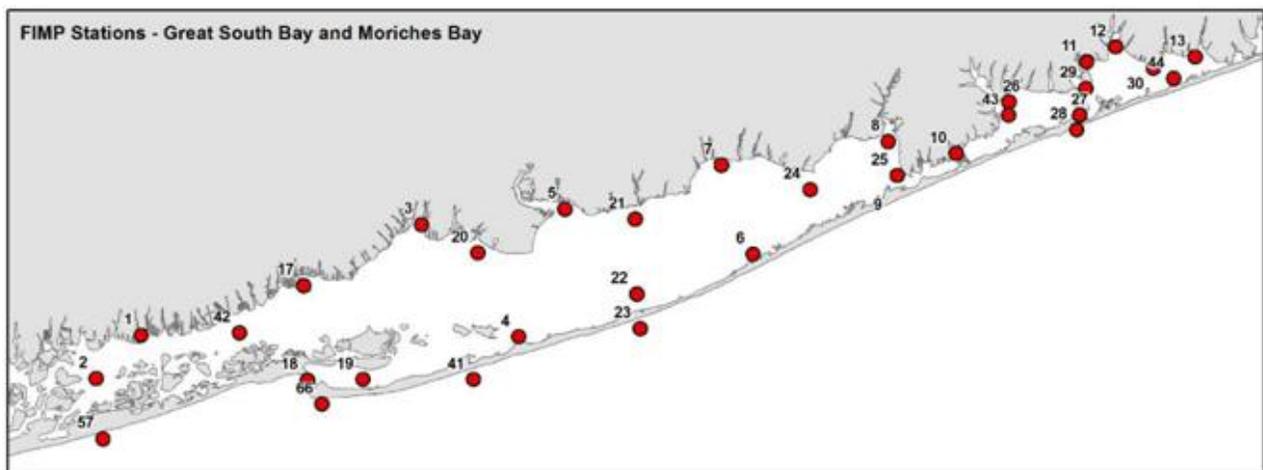

5 Baseline conditions evaluated in initial modeling efforts were representative of the FIMP area
6 topography in 2000. At that time three inlets (Fire Island, Moriches, and Shinnecock) connected the
7 ocean with bays in the FIMP area (Figure 1). Both ADCIRC and Delft3D models were calibrated to
8 astronomical tide and storm water levels collected at established gage locations. The ADCIRC
9 calibration used four National Oceanographic and Atmospheric Administration (NOAA) stations and
10 one Long Island SHORE (LISHORE) station, and the Delft3D model was calibrated using 13 bay
11 area measurement locations (6 in Great South Bay, 4 in Moriches Bay, and 3 in Shinnecock Bay).
12 The Delft3D model was then validated by comparing model results with available high water marks
13 (HWMs) and overwash and breaching data for two of the most significant storms of record: the
14 September 1938 hurricane and the December 1992 nor'easter. The 1938 hurricane made landfall as a
15 Category 3 hurricane on Long Island and represents one of the most powerful and deadliest
16 hurricanes in New England history. The storm caused widespread overwash and created several
17 breaches across the barrier island. The December 1992 nor'easter produced record high water levels
18 across the northeastern United States. On Long Island the storm created two breaches east of
19 Moriches Inlet. Model simulations of the 1938 hurricane produced breaching and overwash in areas
20 similar to the observed storm impacts. Peak water levels from the 1938 simulation matched closely
21 with HWMs recorded in eastern Shinnecock Bay, South Oyster Bay, and central Great South Bay.
22 Model skill was lower in eastern Great South Bay and Moriches Bay where simulated water levels
23 were 30 to 60 centimeters (12 to 24 inches) lower than the HWMs. Modeling of the 1992 nor'easter
24 produced two breaches in the same area as the observed storm impacts. Peak water levels from the
25 1992 simulation either matched or underestimated by 60 centimeters (24 inches) the HWM data
26 recorded in Moriches Bay and Great South Bay. Further to the west in Patchogue and Lindenhurst,
27 the model results were within the reported range of HWMs, although the average reported HWMs
28 were underestimated by approximately 60 centimeters (24 inches). Overall, the model simulations for
29 these two historic storms were considered to provide realistic results, particularly when considering
30 the uncertainty in the input hydrodynamic conditions and, more importantly, the pre-storm
31 topographies.

32 The numerical models were used to simulate water levels in the bays under baseline conditions
33 during 36 historical storms (14 hurricanes and 22 nor'easters), as well as 21 additional storms. These
34 simulations showed that peak water levels in Great South Bay were produced by extratropical storms,
35 while tropical storms generated the highest water levels in Moriches and Shinnecock Bays. Peak
36 simulated water levels in Great South Bay from the tropical storms were on the order of 20
37 centimeters (7.9 inches) lower than those from the extratropical storms. This was attributed to the
38 transference characteristics of Fire Island Inlet. Surge associated with tropical storms that tend to
39 pass through the area more quickly than nor'easters is significantly dampened at Fire Island Inlet,

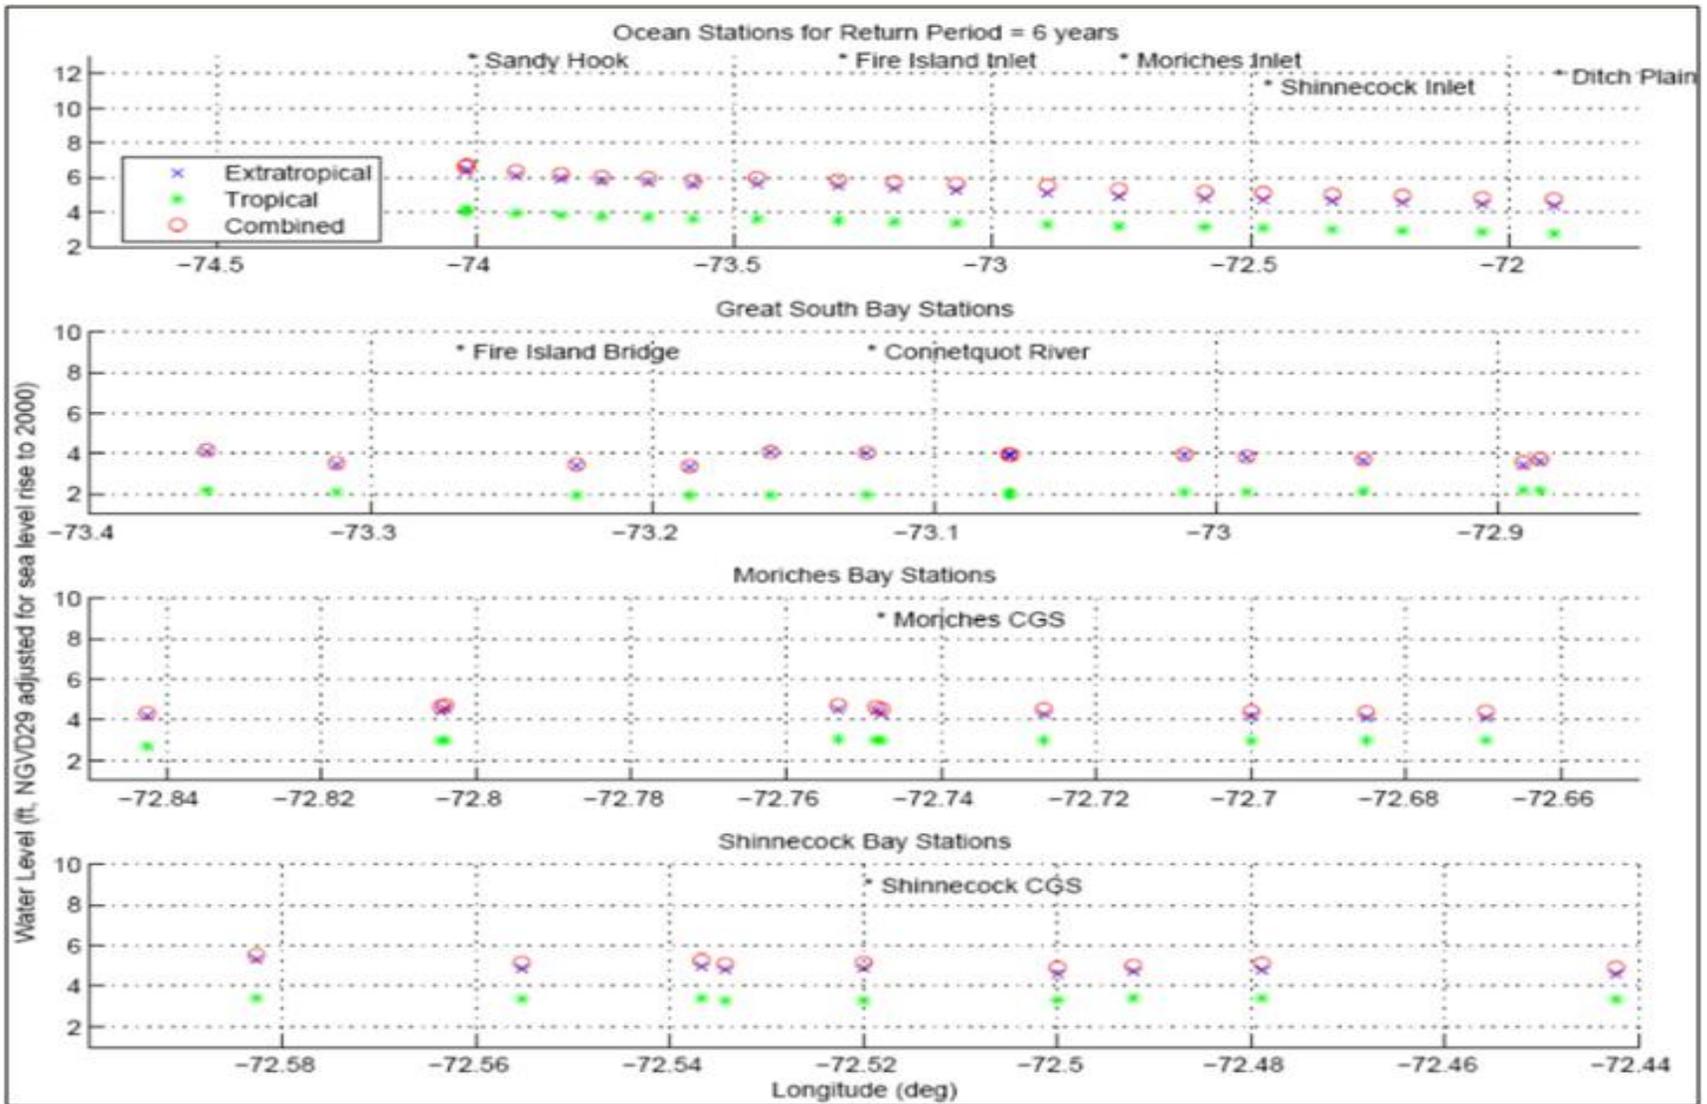

1 while the surge generated by extratropical storms that typically last several tidal cycles increases the
2 total volume of water passing through the inlet, resulting in higher peak water levels.

3 For baseline conditions (pre Sandy), only a small number of storm simulations resulted in significant
4 contributions to water levels in the bays due to overwash/inundation of the barrier island. These same
5 storms were the only ones to produce full breaches or partial breaches of the barrier. Full breaches
6 were considered to be storm-induced cuts through the barrier where scour depth was at or below
7 mean low water (MLW). Partial breaches were considered where the scour depth was between mean
8 high water (MHW) and MLW. The wilderness area, and in particular the site of the breach that
9 formed during Hurricane Sandy, was found to be the most vulnerable spot for full breaching in the
10 FIMP study area, due in large part to the lower elevation of the dunes under baseline conditions. The
11 storm modeling for the 1938 event also resulted in partial breaching at Smith Point County Park,
12 Tiana Beach, and West of Shinnecock Inlet.

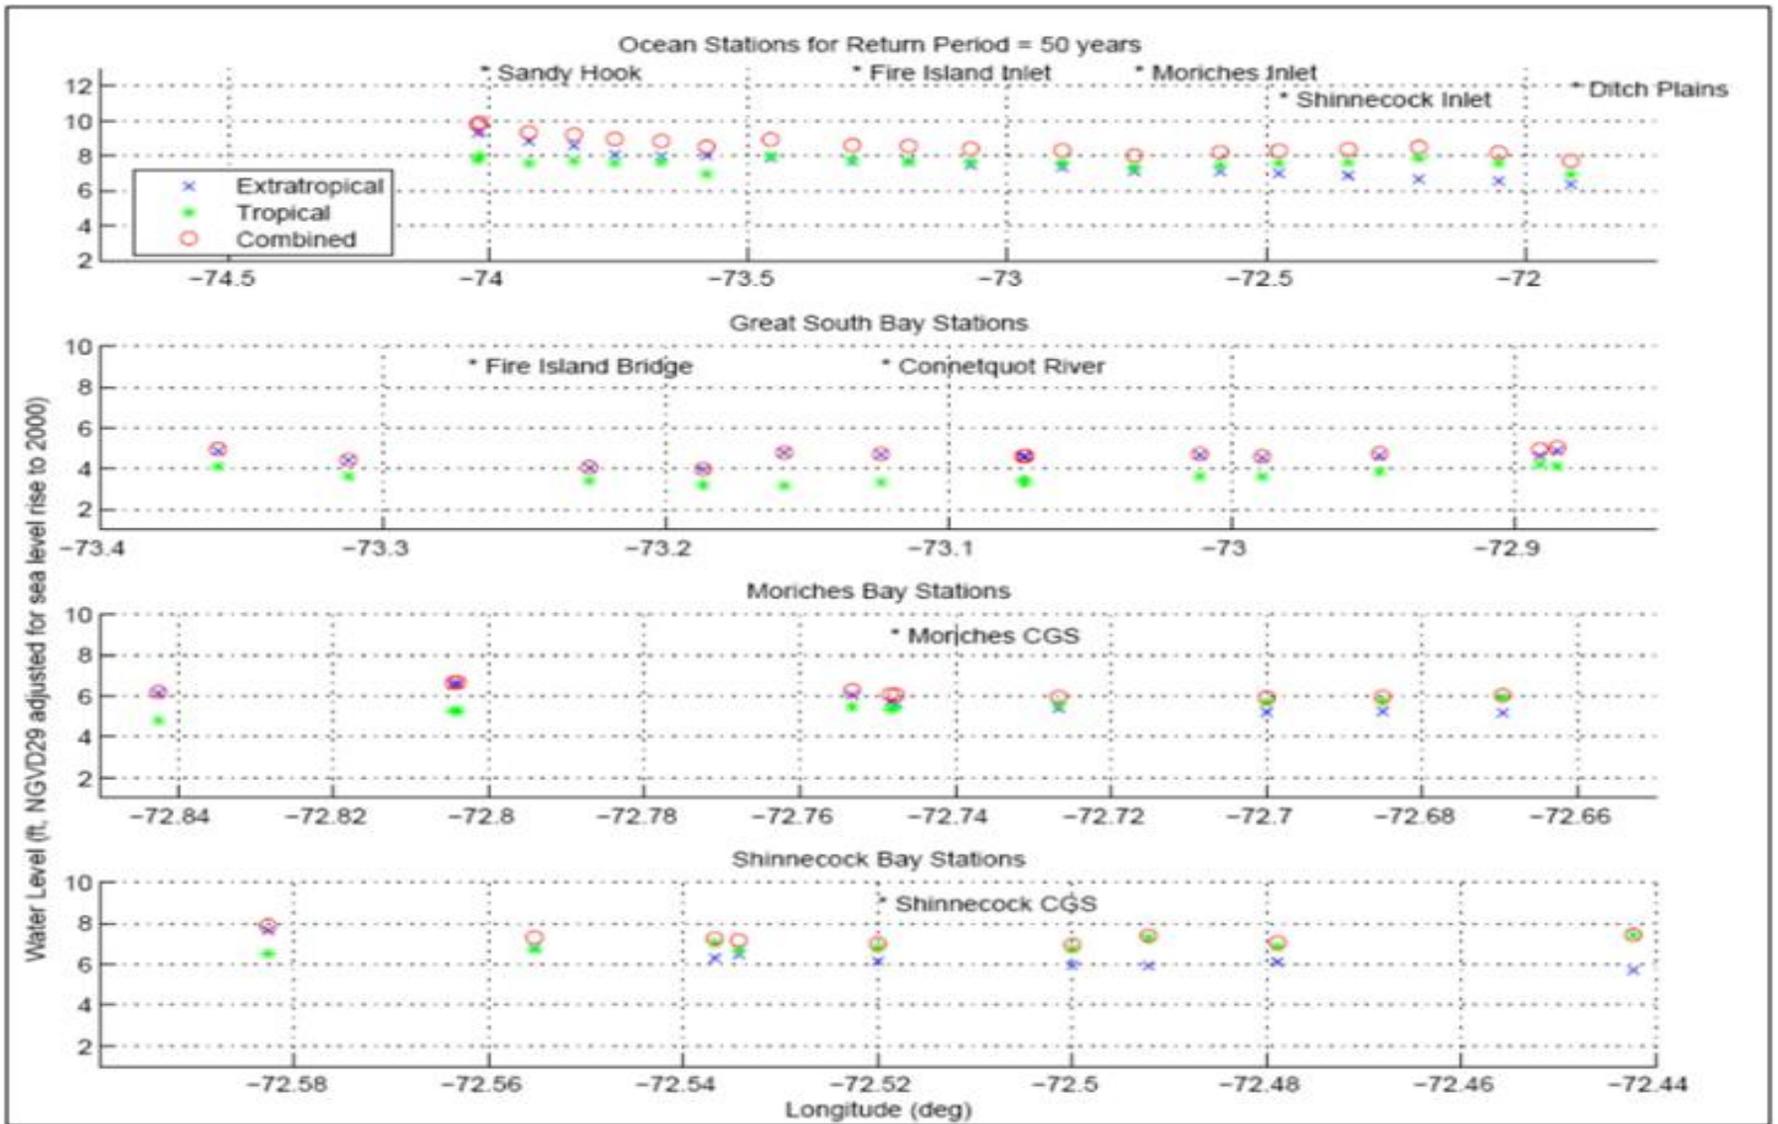

13 Stage-frequency relationships using the modeled water levels for all storm simulations were
14 developed using the one-dimensional Empirical Simulation Technique. Peak water levels (storm
15 surge and tides) at 28 stations in Great South Bay and Moriches Bay for the 6-, 10-, 25-, 50-, 73-, and
16 100-year return periods were developed for the pre Sandy baseline conditions (Figure 2). For Great
17 South Bay the 6-year return period peak water levels were found to be between 1.1 and 1.4 meters
18 (3.6 and 4.6 feet), the 50-year return period peak water levels were between 1.2 and 1.5 meters (3.9
19 and 4.9 feet), and the 100-year return period levels were between 1.2 and 1.8 meters (3.9 and 5.9
20 feet) (NGVD29 adjusted for sea level rise to 2000) (Figures 3–5). Stage frequency results in
21 Moriches Bay were generally higher than those in Great South Bay since Moriches more readily
22 responds to ocean conditions. Peak water levels in Moriches Bay were between 1.2 and 1.5 meters
23 (3.9 and 4.9 feet) for the 6-year return period, between 1.8 and 2.1 meters (5.9 and 6.9 feet) for the
24 50-year return period, and between 2.0 and 2.3 meters (6.6 and 7.5 feet) for the 100-year return
25 period (Figures 3–5). Spatial variations in water levels within the bays were found to be consistent
26 with the bay’s geometry, inlet configurations, and exchange with adjacent water bodies.

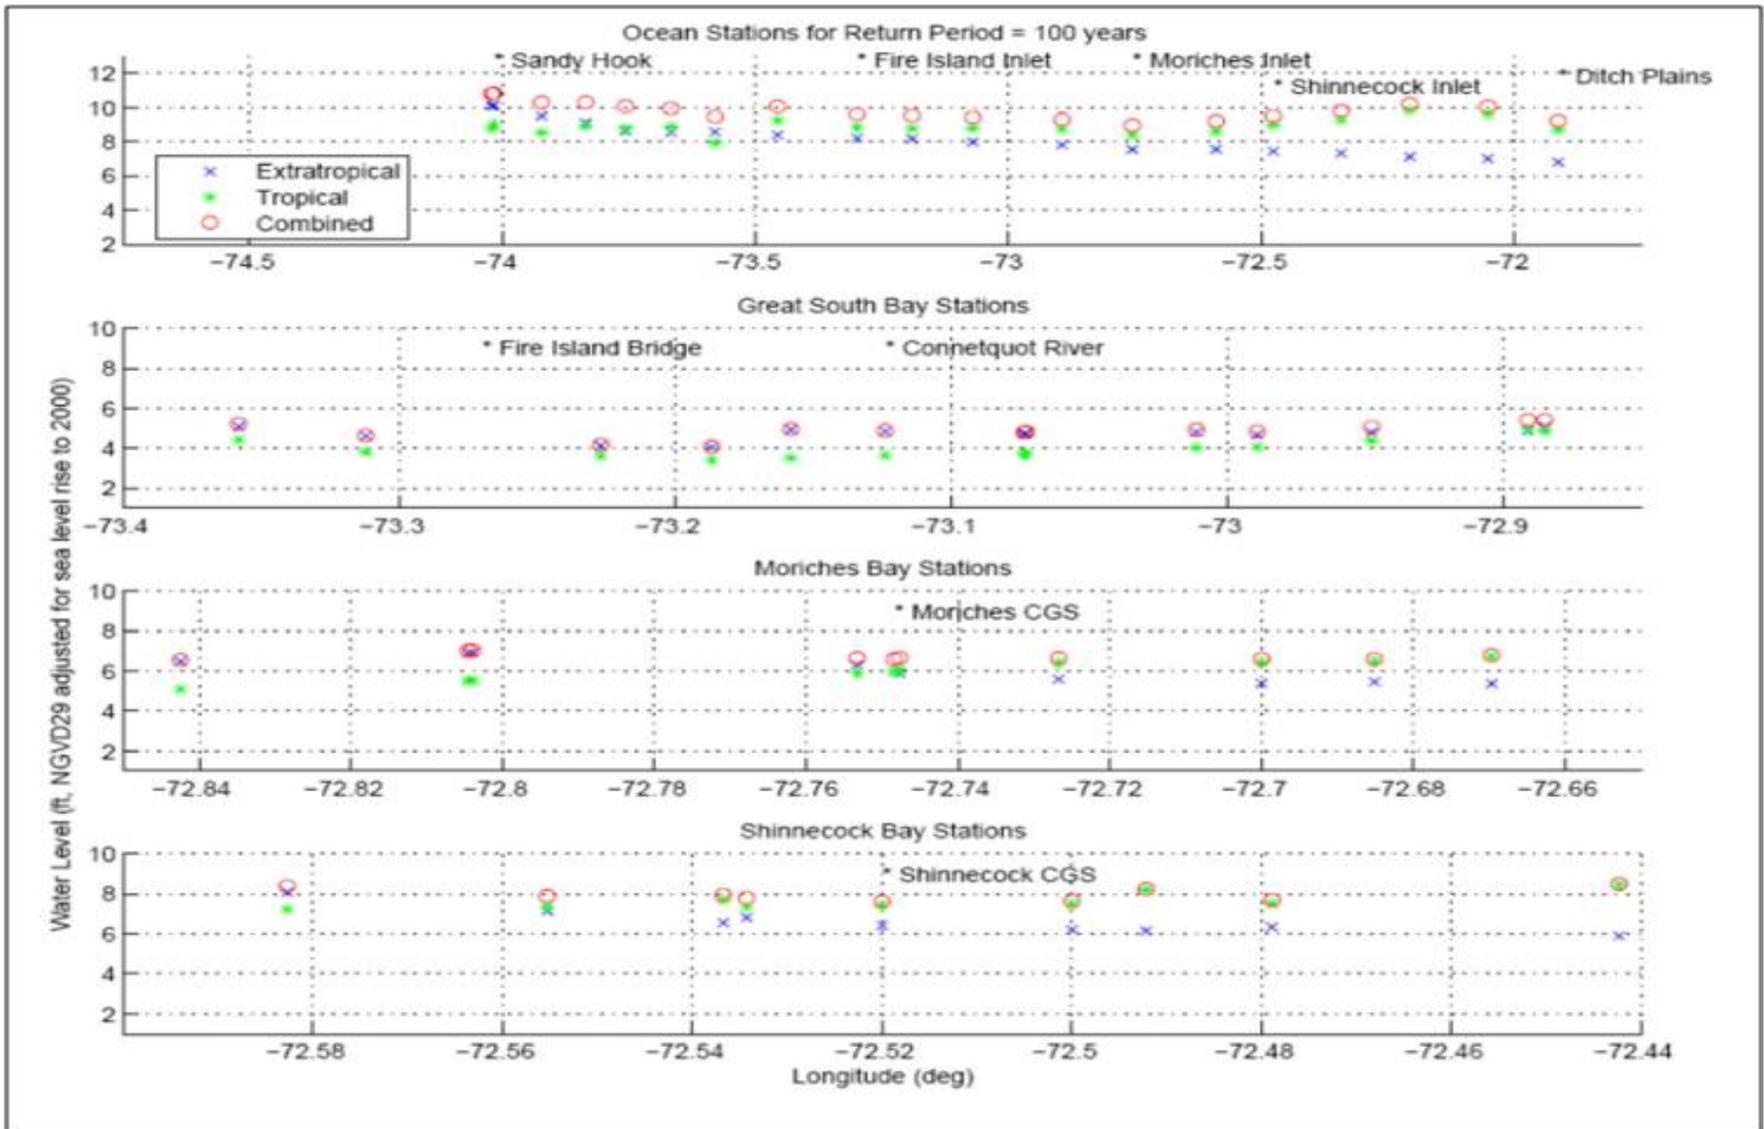

27

 2 **Figure 4.** Spatial distribution of 50-year return period peak water (in feet) levels for baseline conditions (pre Sandy) from USACE modeling
 3 (USACE 2006a).

1
 2 **Figure 5.** Spatial distribution of 100-year return period peak water levels (in feet) for baseline conditions (pre Sandy) from USACE modeling
 3 (USACE 2006a).

1 Additional modeling scenarios were also conducted by the USACE to evaluate the effects of barrier
 2 island breaches on maximum water levels in the bays. The methodology used to select the breach
 3 locations and the different modeling scenarios is summarized in a February 2, 2006, document
 4 entitled *Summary of Development Approach and Draft Results for Baseline, Future Vulnerable, and*
 5 *Breach Closed Conditions Breach/Overwash-Frequency Relationships* (Moffatt & Nichol, Canizares,
 6 and Alfageme 2006), as well as a March 22, 2006 Memorandum prepared by Moffat & Nichol
 7 (Author Unknown 2006). At this time, 12 representative breach open scenarios were evaluated for
 8 six select storms. The smaller number of storms was considered sufficient to provide enough
 9 information to create stage frequency curves for the bays under the different breach open scenarios.
 10 The 12 breach open scenarios were comprised of 4 representative location-based scenarios with three
 11 possible breach sizes corresponding to estimated widths at 3, 6, and 12 months from breach
 12 formation. The widths were 762 meters (2,500 feet), 1,128 meters (3,701 feet), and 1,433 meters
 13 (4,701 feet) for the 3-, 6-, and 12-month scenarios, respectively. All scenarios assumed a breach
 14 depth of 2.1 meters (6.9 feet) (mean sea level). The breach open condition (BOC)-1 scenario
 15 included a breach in eastern Great South Bay in the vicinity of the current wilderness breach and a
 16 second breach in western Shinnecock Bay. The other scenarios considered multiple breaches or
 17 openings in western and central Great South Bay, eastern Moriches Bay, and Shinnecock Bay
 18 (Table 2). Results from the model simulations were used to prepare stage frequency curves for bay
 19 stations in the FIMP area, given the different breach scenarios.

20 **Table 2.** Four location-based scenarios considered for breach open modeling simulations. Wilderness
 21 breach is represented by the Eastern Great South Bay location.

| Breach Open Conditions for Numerical Simulations | | | | | | |
|--|-------------------------|-------------------------|-------------------------|----------------------|------------------------|----------------|
| Breach Open Scenario | Western Great South Bay | Central Great South Bay | Eastern Great South Bay | Eastern Moriches Bay | Western Shinnecock Bay | Shinnecock Bay |
| BOC-1 | | | X | | X | |
| BOC-2 | X | | | X | X | |
| BOC-3 | | X | | | | X |
| BOC-4 | X | | X | X | | X |

22 Following formation of the wilderness breach in 2012, the USACE modeling was updated to validate
 23 the integrity of the earlier modeling efforts and to examine applicability of the modeling approach to
 24 the wilderness breach. This recent work was documented in a Draft Memorandum from Moffatt &
 25 Nichol dated September 11, 2015. The updated work included revalidation of the model with breach
 26 closed conditions and validation to conditions with the wilderness breach. Model simulations were
 27 conducted to evaluate impacts on tides and storm tides with various BOCs, and the stage frequency
 28 curves for bay water levels were updated to reflect the influence of the wilderness breach.

29 Post Hurricane Sandy modeling was performed using new versions of the Delft3D software and the
 30 updated Simulating WAVes Nearshore (SWAN) model. Revalidation was conducted using baseline
 31 conditions (breach closed) and the model was found to accurately reproduce tidal propagation in the
 32 bays, flow through the inlets (Fire Island and Moriches), and the effects of winds, waves, and surge
 33 propagation during the blizzard of 2003.

1 The updated model was validated by running a 2-year simulation from November 1, 2012, to
 2 November 1, 2014, using breach bathymetry from a June 2014 USGS survey (Nelson et al. 2016a).
 3 At the time of the 2014 survey the breach was approximately 305 meters (1,001 feet) wide at its
 4 narrowest point. The 2014 surveyed breach condition was used in a separate modeling study by the
 5 USGS (discussed later in this section), allowing for comparison of results from the two model
 6 studies. Model validation was performed for a 2-month period in early 2014 by comparing tidal
 7 constituents from four water level gages in Great South Bay with tidal constituents predicted by the
 8 model. The validation showed good agreement between the observed and modeled data. For storm
 9 conditions, the model showed a slight over-prediction in peak bay water level, by as much as
 10 25 centimeters (9.8 inches) at one location, but was considered representative given uncertainties in
 11 model bathymetry and boundary conditions. It was noted that differences between modeled and
 12 observed storm water levels were consistent with those found with the Deltares model (van Ormandt
 13 et al. 2015). It was also noted that model bathymetry from the June 2014 survey could have caused
 14 the over-prediction in peak bay water levels during the first months of the simulation, since the
 15 breach grew in size rapidly between Hurricane Sandy and the time of the survey.

16 To assess impacts of the wilderness breach on tides and small storm tides in the bay, the 2-year
 17 simulation (November 1, 2012 to November 1, 2014) was repeated with “breach closed” conditions.
 18 The breach was found to have a very small effect on daily tidal fluctuations and small storm tides.
 19 Changes to the daily tide at Fire Island Inlet, Tanner Park, and Bellport (Figure 1), as determined by
 20 absolute changes in the modeled M2 tidal constituent and MHW, were all less than 0.8 centimeters
 21 (0.3 inches). At Lindenhurst (Figure 1) the increase was slightly greater at approximately
 22 2.7 centimeters (1.1 inches) (Table 3). These results are consistent with the Deltares modeling
 23 performed by van Ormandt et al. (2015).

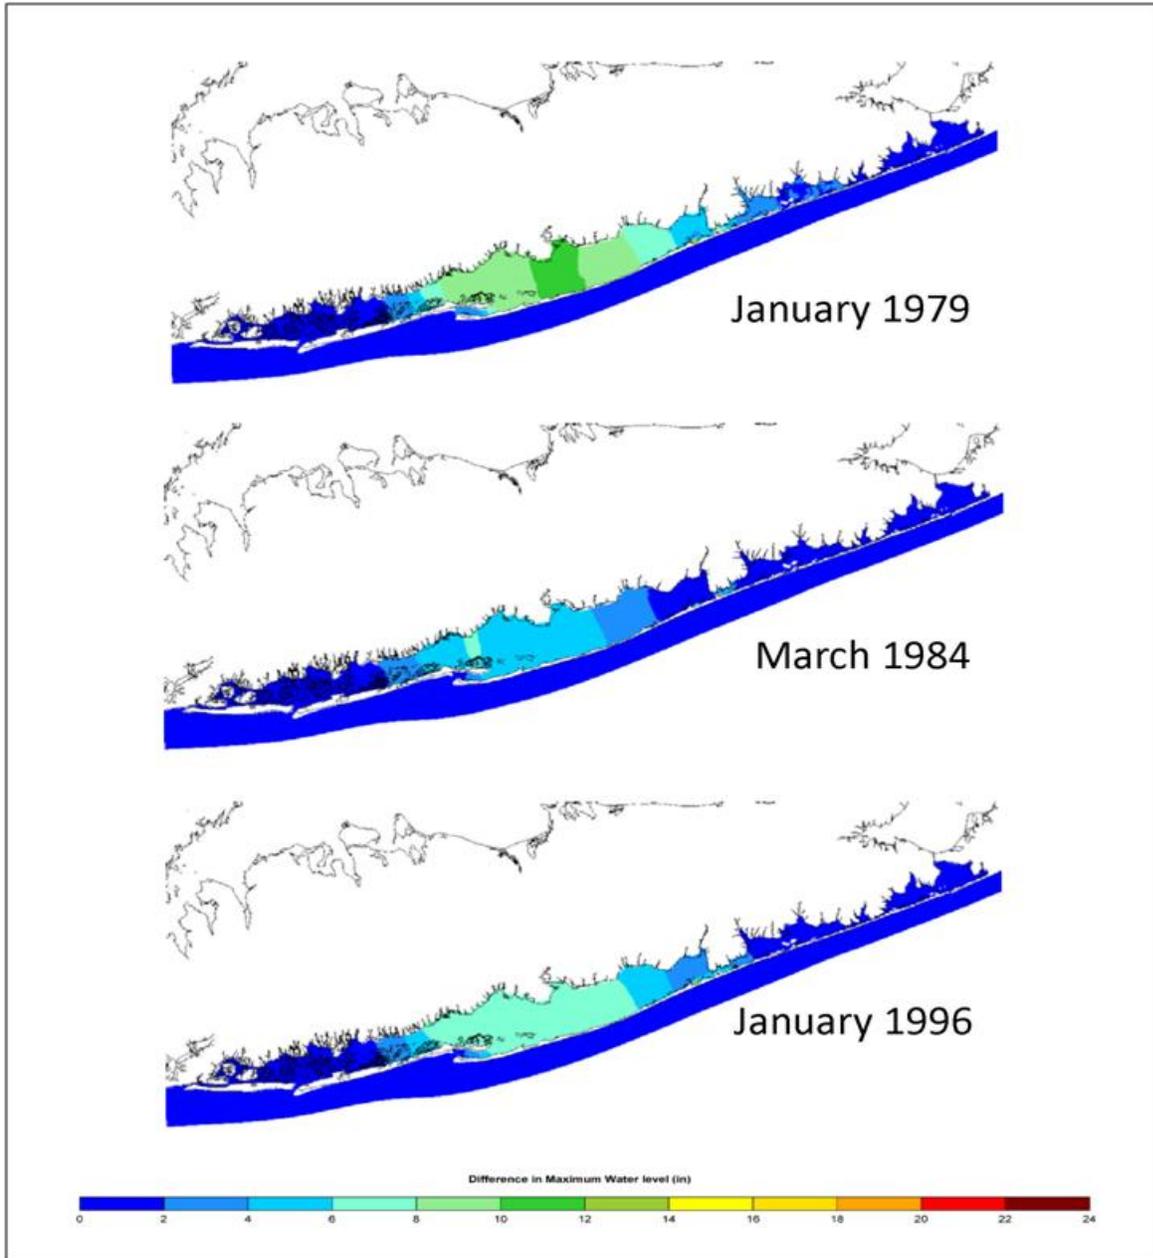

24 **Table 3.** Impact to tides of breach open at the wilderness breach.

| Station | Absolute Change in Centimeters (Inches) | | Percent Change | |
|-------------------|---|-------------|----------------|-------|
| | M2 | MHW | M2 | MHW |
| Fire Island Inlet | 0.2 (0.08) | 0.2 (0.08) | 0.9% | 0.8% |
| Tanner Park | 0.8 (0.3) | 0.8 (0.3) | 3.5% | 3.5% |
| Bellport | -0.2 (-0.08) | -0.2(-0.08) | -1.3% | -1.2% |
| Lindenhurst | 2.7 (1.1) | 2.87 (1.13) | 19% | 19.0% |

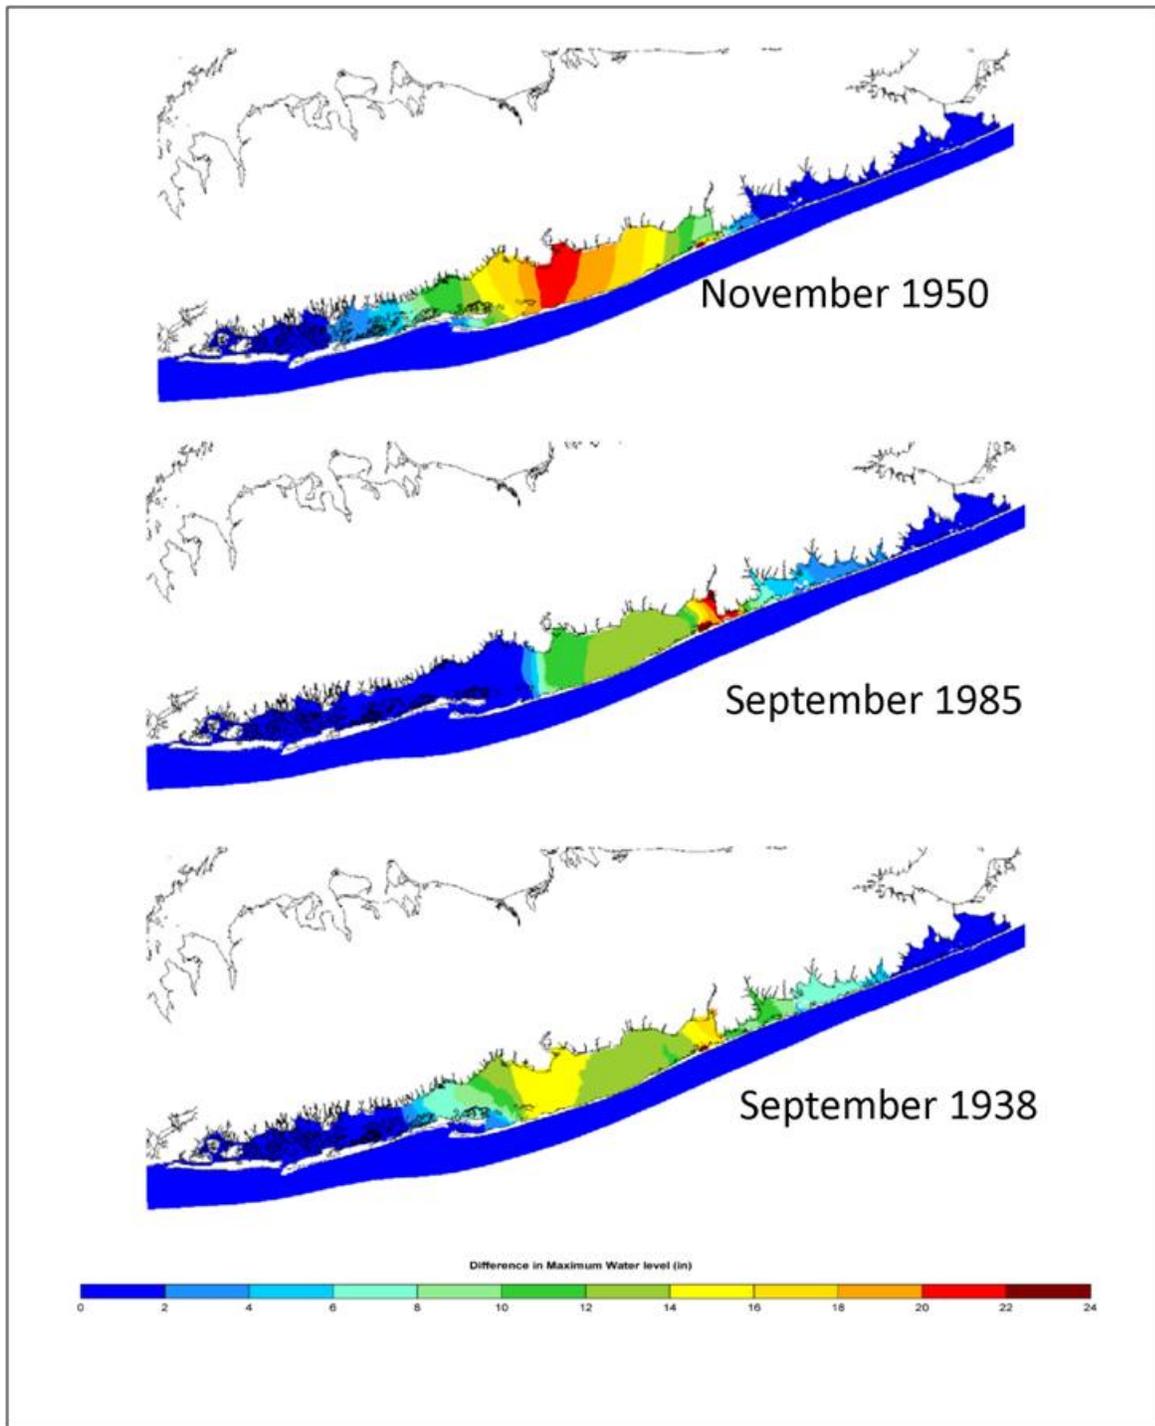

25 Model results showed that the wilderness breach had a similar effect on small storm tides (i.e., tides
 26 plus storm surge). Simulations on two small storms in December 2012 showed that peak storm tides
 27 at Lindenhurst and Bellport were 2.5 to 7.6 centimeters (1.0 to 3.0 inches) higher with the breach
 28 open. Overall however, linear regression analyses on the entire 2-year simulation showed an increase
 29 in small storm peak water levels at Lindenhurst, and a slight decrease at Bellport.

30 Impacts of the breach on water levels during large storm events were evaluated by simulating six
 31 storm events. The storms selected were considered sufficient to update the stage frequency curves
 32 produced during the original 2006 modeling for the FIMP bay areas using the different breach open
 33 scenarios (i.e., 3-, 6-, and 12-month scenarios). Increases in maximum water level between the

1 breach closed and the June 2014 BOC for these storm events were found to be as high as 25.4
2 centimeters (10 inches) during the smaller storm events and up to 55.9 centimeters (22.0 inches)
3 during the larger storm events (Figures 6 and 7). The highest water levels generally occurred near the
4 center of Great South Bay. The model predictions of increased water levels during storms represent
5 order of magnitude increases rather than absolute values. The dynamic and constantly changing
6 nature of the breach, including variations in morphology since the June 2014 survey which have
7 decreased the width, hinder predictions of absolute water levels with a numerical model; however the
8 order of magnitude for water level increases shown by the model is considered reliable.

9
10 **Figure 6.** Comparison of modeled peak water levels during small storms with and without breach (Moffatt
11 & Nichol and Canizares 2015). Extratropical storms: January 1979, March 1984, and January 1996.

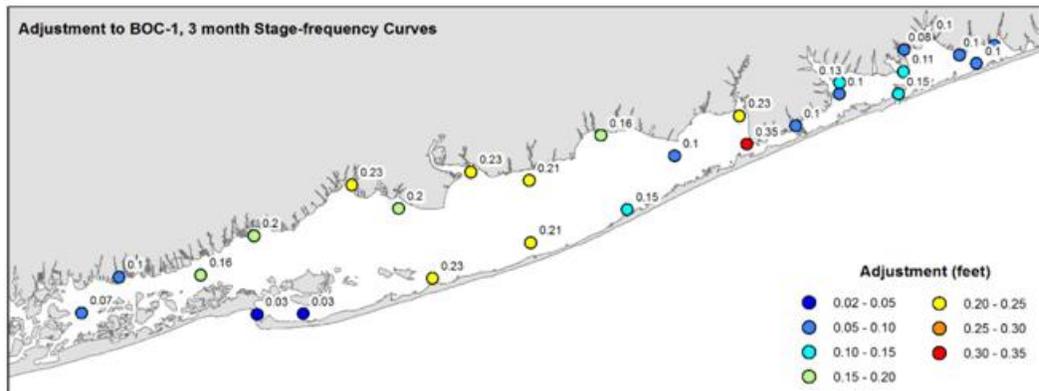

1

2 **Figure 7.** Comparison of modeled peak water levels during large storms with and without breach (Moffatt
 3 & Nichol and Canizares 2015). Tropical storms: September 1938 and September 1985; Extratropical
 4 storm: November 1950.

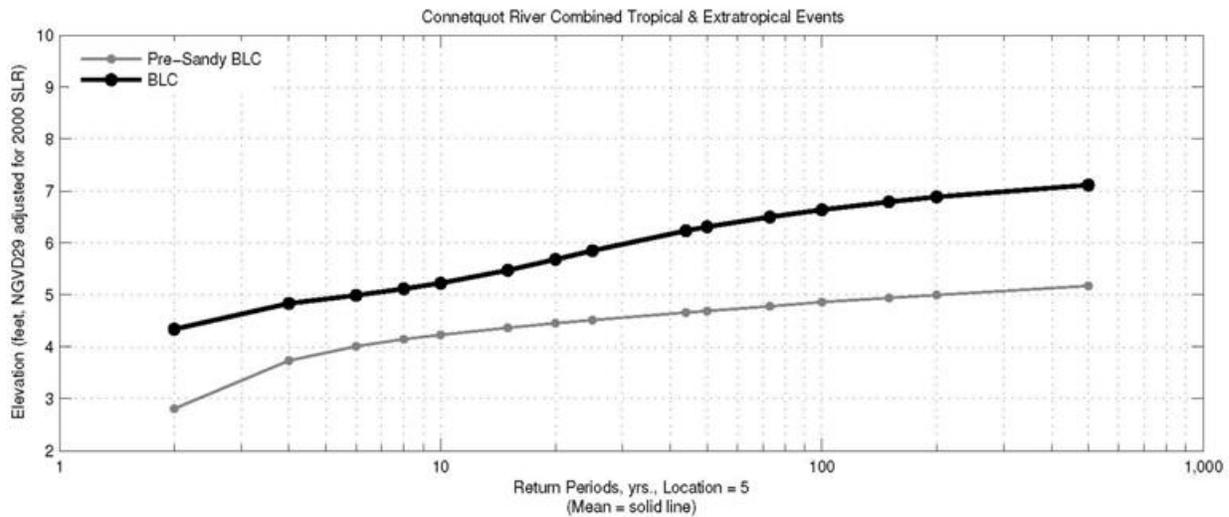

5

1 Given the persistence of the wilderness breach since initial formation in 2012, the USACE revised
2 the pre Sandy baseline conditions to reflect the wilderness breach as of June 2014. Revised baseline
3 stage frequency curves were based on the BOC-1 (3-month) curves (developed in 2006). Although
4 the width of the BOC-1 (3-month) breach was nearly 2.5 times larger than the June 2014 breach, the
5 model simulations showed similar impacts on bay water levels in terms of magnitude and spatial
6 extent. Analyses comparing relative increases in bay water levels caused by the BOCs versus return
7 period showed slightly greater water levels at higher return periods for the June 2014 breach. This
8 was thought to be related to increased conveyance through the deeper and better defined channels
9 represented in the June 2014 breach and model bathymetry, as compared to the simple rectangular
10 breach geometry used to represent the BOC-1 (3-month) condition. Comparative analyses for all
11 model stations in Great South Bay and Moriches Bay were used to identify adjustments for shifting
12 the BOC-1 (3-month) stage frequency curves. Adjustments to the BOC-1 (3-month) curves varied by
13 station and generally ranged between 0.9 and 10.1 centimeters (0.4 and 4 inches), with the greatest
14 water level increases occurring in the vicinity of the wilderness breach (Figure 8).

15
16 **Figure 8.** Adjustment values by station to BOC-1, 3-month stage frequency curves to reflect June 2014
17 breach open conditions.

18 Comparison between stage frequency curves for the 2006 and 2014 baseline conditions at stations
19 throughout Great South Bay and Moriches Bay showed a maximum 100-year return period water
20 level increase of 60 centimeters (23.6 inches) at Station 5 near the mouth of the Connetquot River
21 (Figure 9). Increases elsewhere in Great South Bay and Moriches Bay for the 100-year return period
22 were between 20 and 40 centimeters (7.9 and 15.7 inches).

1
 2 **Figure 9.** Stage frequency curve for Station 5 near the Connetquot River showing differences in water
 3 levels between the 2006 Pre-Sandy baseline condition (no breach) and the 2014 baseline condition (with
 4 breach) conditions (Moffatt & Nichol and Canizares 2015).

5 Geospatial data developed by the USACE from stage frequency curves for the 2-, 10-, and 100-year
 6 return period storms using the 2006 and 2014 baseline conditions show areas of increased flooding
 7 around Great South Bay and Moriches Bay that may result from the breach. When comparing
 8 baseline conditions for the 2-year storm event, the model predicts a potential increase in flooded area
 9 of approximately 3,825 acres (2014 baseline with 2-year storm minus 2006 baseline with 2-year
 10 storm). During the 10-year storm event the flooded area may potentially be increased by
 11 approximately 970 acres, and during the 100-year event the flooded area may be increased by 2,790
 12 acres. The affected areas likely contain a mixture of land use types (e.g., residential, open space,
 13 commercial) although the distribution was not quantified in the geospatial datasets.

14 To evaluate potential impacts to water levels from wider breaches, the USACE ran model
 15 simulations with BOC-1 conditions for 6 and 12 months. The 6-month condition used a breach width
 16 of 1,128 meters (3,700 feet) and the 12-month condition used a breach width of 1,433 meters (4,701
 17 feet). All scenarios assumed a breach depth of 2.1 meters (6.9 feet) (mean sea level). Results from
 18 these simulations showed maximum water level increases of 80 centimeters (31 inches) for the 100-
 19 year return period (Bocamazo pers. comm. 2016). The 6- and 12-month breach scenarios represent
 20 openings 1.5 to 2.0 times larger than the BOC-1 (3-month) condition, and approximately 3.6 to 4.6
 21 times larger than the June 2014 breach. Given the history since formation in 2012, enlargement of the
 22 breach 3.6 to 4.6 times its June 2014 width would represent a dramatic change in breach evolution.
 23 The modeled scenarios may be more representative of future storm water levels under climate change
 24 and sea level rise conditions.

25 **US Geological Survey/Deltares Model Studies**

26 Post Hurricane Sandy modeling of Fire Island and the surrounding areas has been conducted by
 27 Deltares with geospatial data required for model runs provided by the USGS. The work has focused

1 on studying the changes in morphology of the breach and its impacts on the neighboring areas.
2 Modeling capabilities for predicting stability of future breaches on Fire Island or other similar
3 environments were also developed. Information on the numerical modeling aspect of the work is
4 contained on the Deltares Fire Island web site (www.cosmos.deltares.nl/FireIsland/index.html) and a
5 journal article entitled *The Effects of Geomorphic Changes during Hurricane Sandy on Water Levels*
6 *in Great South Bay* (van Ormondt et. al. 2015).

7 The model approach included a series of nested hydrodynamic and spectral wave models in
8 combination with a model for simulating sediment transport and morphological change. The
9 following combinations of numerical models were used:

- 10 • DFlow-FM to simulate tidally generated and storm induced water levels in the ocean and
11 nearshore areas,
- 12 • SWAN to develop 2D spectral wave conditions,
- 13 • XBeach to simulate dune and beach erosion and overwash volumes, and
- 14 • Delft3D-FLOW/SWAN to simulate water levels, waves, and changes in morphology in Great
15 South Bay (referred to as Great South Bay model).

16 Forcing at the boundaries was accomplished by imposing water levels and waves from a series of
17 larger scale models. The Delft3D models were used during relatively calm periods when offshore
18 waves heights were less than 3.5 meters (11.5 feet), and the XBeach model was used during storms.
19 Model simulations were initially run to reproduce conditions during Hurricane Sandy. Subsequent
20 model runs were conducted for a 2-year period from November 2012 (post Hurricane Sandy) to
21 October 2014.

22 Model results for the Hurricane Sandy simulation showed agreement between computed and
23 observed water levels at the Battery, New York, NOAA station, although the peak of the surge was
24 underestimated by 27 centimeters (10.6 inches). The storm simulation also showed the highest
25 volumes of overwash (water) at the western end of Fire Island, the eastern portion of the island near
26 the wilderness breach, and just west of Moriches Inlet. Overall however, the total volume of water
27 flowing over the barrier beach was small compared to the volume flowing through the main inlets.

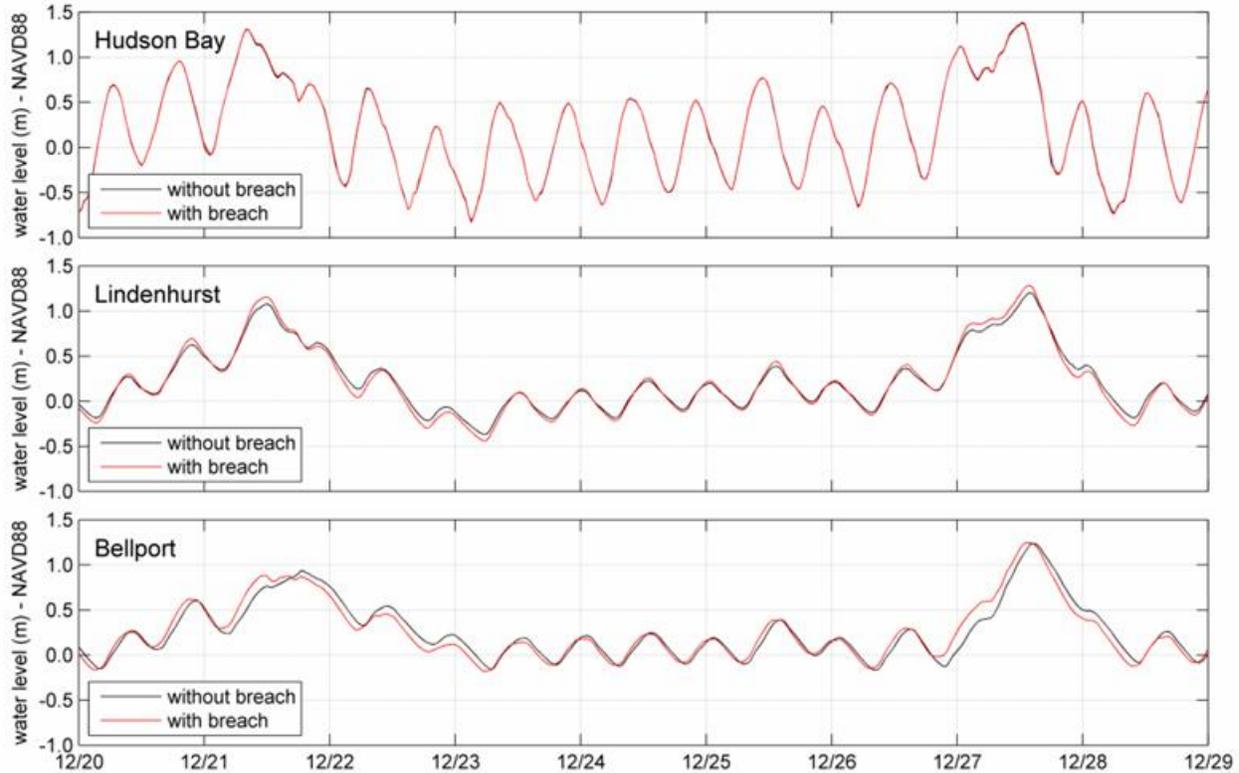

28 A number of experiments were conducted on the Great South Bay model to evaluate the effect of
29 different processes on water levels in Great South Bay during Hurricane Sandy. The tests were
30 designed to assess the influence of short waves and overwash contributions on bay water levels. The
31 sensitivity testing showed that peak water levels in Great South Bay were increased by
32 approximately 20–50 centimeters (7.9 to 19.7 inches) by adding wind-generated waves, and this
33 improved the match between modeled and observed water levels. Addition of overwash volumes
34 added approximately 20 centimeters (7.9 inches) to the peak water levels, and this resulted in an
35 over-prediction in water levels west (Lindenhurst) and east (Narrow Bay) of the breach.

1 Additional sensitivity testing has been conducted using Hurricane Sandy forcing to assess the effects
 2 of a significantly wider breach configuration on water levels in Great South Bay. These preliminary
 3 results are expected to be released for publication in 2016.

4 To evaluate effects of the wilderness breach on water levels in the bays, the Great South Bay model
 5 was run both with and without the breach over the 2-year period immediately following Hurricane
 6 Sandy to October 2014. The model for the with breach simulations was run with a fixed bathymetry
 7 based on a June 2014 USGS survey of the breach. Linear regression analyses of twice-daily high
 8 water levels and small storm surge levels, as well as tidal analysis of the computed time series from
 9 the model were performed to evaluate effects of the breach. Daily peak water and surge levels in
 10 Hudson Bay at the far western end of the system were not affected by the breach. At Lindenhurst
 11 near the western end of Great South Bay, the model showed an increase of 2.6 centimeters (1.0 inch)
 12 in daily high water levels with the breach, and at Bellport (eastern Great South Bay) there was an
 13 increase of 0.3 centimeters (0.11 inches) (Table 4 and Figure 1). Surge levels with the breach
 14 increased by 4.2% at Lindenhurst and 1.3% at Bellport. A comparison between computed water levels
 15 with and without the breach at each station for a 9-day period in December 2012 illustrates the
 16 effects of the breach on daily water levels and small surge events (Figure 10).

17 **Table 4.** Impact on tidal amplitude and phase with and without the breach.

| Station | Observed | | Modeled without Breach | | Modeled with Breach | |
|-------------|--------------------|----------|------------------------|----------|---------------------|----------|
| | Amplitude (m / ft) | Phase(°) | Amplitude (m / ft) | Phase(°) | Amplitude (m / ft) | Phase(°) |
| Hudson Bay | 0.566 / 1.9 | 9.1 | 0.620 / 2.0 | 10.9 | 0.618 / 2.0 | 11.0 |
| Lindenhurst | 0.172 / 0.6 | 71.8 | 0.169 / 0.6 | 83.4 | 0.195 / 0.6 | 85.2 |
| Bellport | N/A | N/A | 0.166 / 0.5 | 108.0 | 0.163 / 0.5 | 91.0 |

1
2 **Figure 10.** Comparison of computed (modeled) water levels with and without the breach for Hudson Bay,
3 Lindenhurst, and Bellport for the period of December 20–29, 2012 (van Ormondt et al. 2015).

4 Tidal constituent analyses on the model results showed that tides were unaffected by the breach at the
5 far western end of the system in Hudson Bay. At Lindenhurst in western Great South Bay, the
6 amplitude of the M2 component increased by 15% and there was a small phase shift of +2°. The tidal
7 analysis at Bellport showed a 2% increase in M2 amplitude and a phase shift of -17°. The modeling
8 indicated that high and low waters in Bellport occur approximately 35 minutes sooner as a result of
9 the breach (Table 4).

10 Results of the 2-year model simulation showed that daily high tides and small storm surge levels in
11 Great South Bay have been minimally impacted by the breach. While both changes are of similar
12 order of magnitude, the changes are small relative to total water level variations in the bay. In the
13 period between Hurricane Sandy and June 2014, the model suggests that the breach did not increase
14 peak water levels by more than 10 centimeters (3.9 inches) at any time (van Ormondt et al. 2015).

15 **US Geological Survey Data Analyses**

16 The USGS working in conjunction with Integrated Statistics conducted a study to evaluate whether
17 the wilderness breach influenced maximum water levels in Great South Bay following Hurricane
18 Sandy (Aretxabaleta, Butman, and Ganju 2014). The study used offshore water level data measured
19 at Sandy Hook, New Jersey, The Battery, New York, and bay water levels measured at Lindenhurst,
20 New York. Data spanning the period from October 1, 2007, to December 31, 2013, were obtained to
21 cover pre- and post-breach conditions. Analyses were performed for tidal amplitudes, spectra of

1 water level fluctuations, and spectral coherence and transfer functions between offshore and bay
2 water levels before and after Hurricane Sandy. Comparisons between water levels before and after
3 Hurricane Sandy at Lindenhurst and offshore stations showed no significant differences in the
4 transfer of sea level fluctuations from offshore to Great South Bay. High water levels in the bay were
5 attributed to winter storms and not the breach or geomorphic changes in Great South Bay caused by
6 Hurricane Sandy. Coherence, transfer coefficients, and regression between water levels in the bay
7 and offshore suggested that water levels in the bay were mostly damped co-oscillations driven by
8 offshore sea level, modified by the duration of offshore events and by the breach and bay geometry.

9 ***Stony Brook University – School of Marine and Atmospheric Sciences Model Studies***

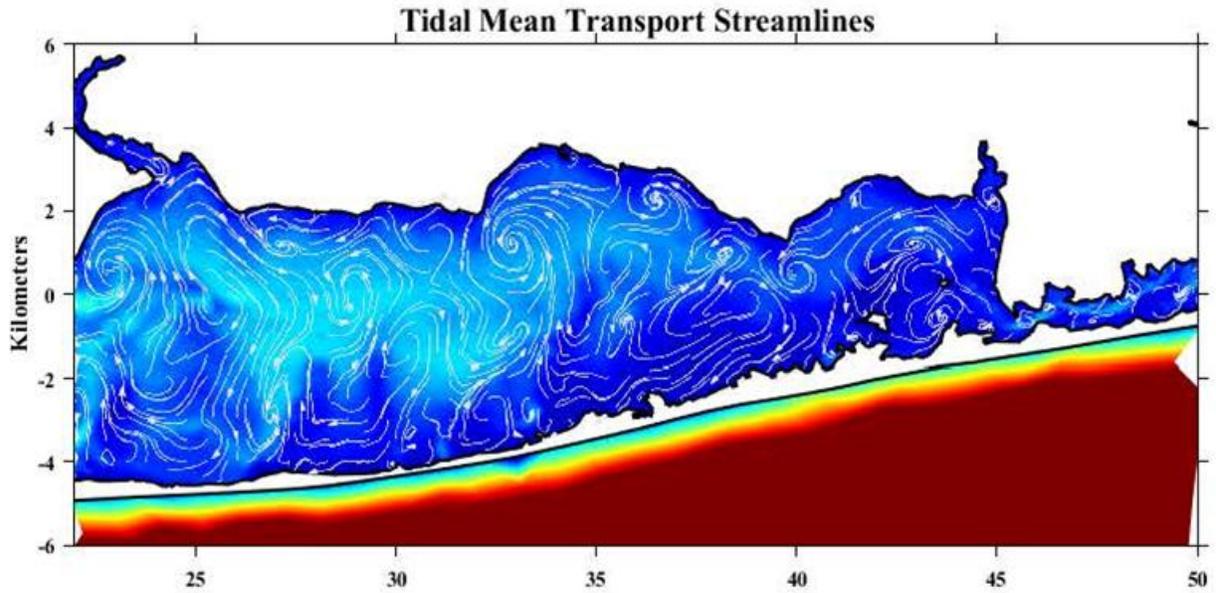

10 Stony Brook University’s School of Marine and Atmospheric Sciences (SoMAS) runs the Great
11 South Bay Observatory, which monitors water levels, temperature, and salinity at several stations
12 around the bay and at the buoy anchored in the central bay. The buoy also measures meteorological
13 conditions. The Great South Bay Project at SoMAS has been studying the hydrodynamics,
14 biochemistry, and benthic and pelagic ecology before and after the opening of the breach. The work
15 combines field observations with numerical modeling to develop an ecosystem based management
16 approach for addressing ecological problems in Great South Bay. As part of this program the Finite
17 Volume Coastal Ocean Model (FVCOM) was set up to examine the structure of tidal and wind-
18 driven circulation in Great South Bay and to evaluate the impacts that breaches in the barrier island
19 could have on the ecology of the bay (Yang 2014; SoMAS 2016).

20 Early model development concentrated on replicating tidal and salinity measurements for baseline
21 conditions (no breach) which included the four tidal inlets from East Rockaway to Moriches Inlet.
22 The model was forced with the following data to quantify the physical processes:

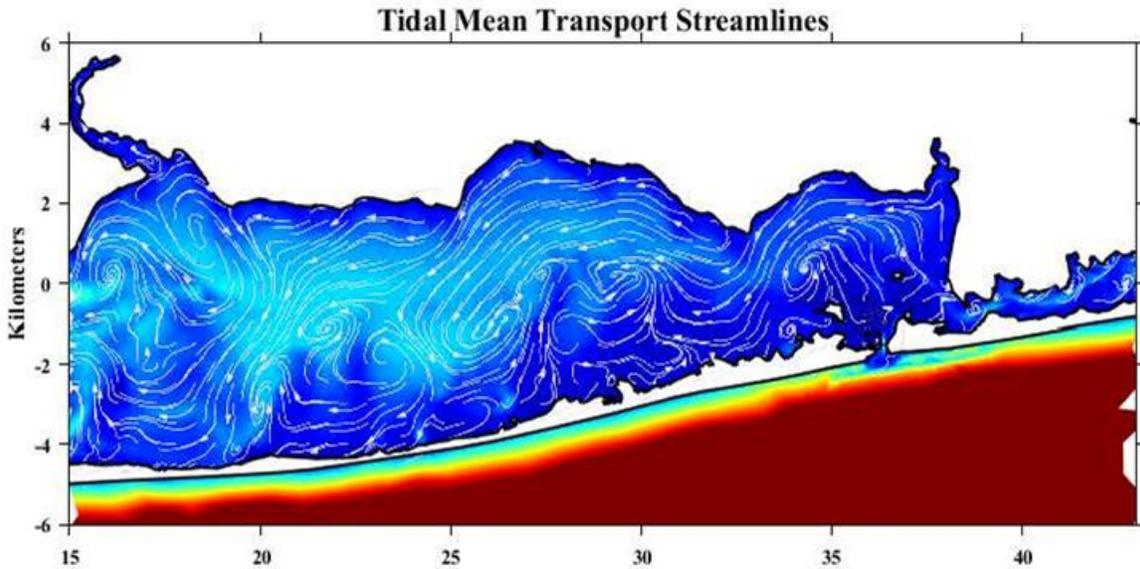

- 23 • Tidal forcing with six constituents from the Oregon State University tidal model,
- 24 • Freshwater inflow from 61 rivers, streams and outfalls along the north shores of Great South
25 Bay and Moriches Bay,
- 26 • Groundwater discharge along the north shores of the bays, and
- 27 • Water temperature and salinity measured at 21 stations in Great South and Moriches Bays
28 and 1 long-term station just outside Fire Island Inlet.

29 For the baseline condition (no breach) the model was used to identify tidal- and depth-averaged
30 velocities and residual currents (tidal-mean transport). The mean current data showed the largest
31 residual currents in the inlets, the channels along the north shore of the western bay, and in Smith
32 Point Channel. Residual currents were much smaller in the open central portion of the bay. A mean
33 inflow was identified in the three smaller inlets (East Rockaway, Jones, and Moriches) with an
34 outflow through Fire Island Inlet. Thus, the model showed that the western and eastern ends of the
35 bay were supplying more saline water to the central bay, in order to maintain the salinity balance
36 against the influence of the larger rivers. The tidal-mean transport for the baseline condition,
37 represented by transport streamlines in Figure 11, showed a number of residual eddies in the open
38 portion of central and eastern Great South Bay. Most of the headlands were also shown to have an

1 associated eddy, and a large counterclockwise eddy was identified south of Patchogue (~33 to
2 34 kilometers (21 miles) on Figure 11).

3
4 **Figure 11.** Tidal mean transport in eastern Great South Bay for the baseline condition (no breach) as
5 simulated by the School of Marine and Atmospheric Sciences Model Studies Finite Volume Coastal
6 Ocean Model for Great South Bay (SoMAS 2016).

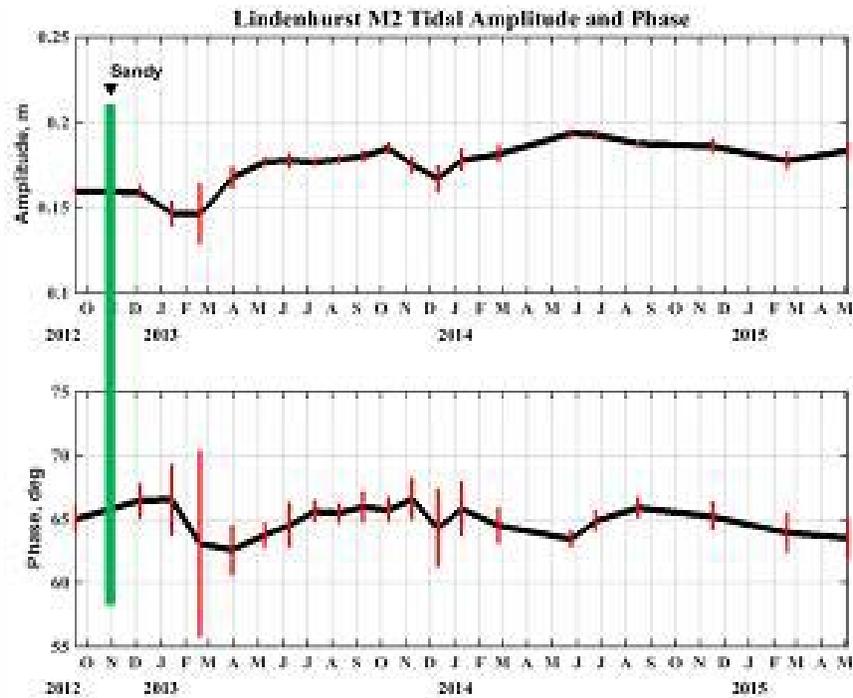

7
8 **Figure 12.** Tidal mean transport in eastern Great South Bay with the breach open as simulated by the
9 School of Marine and Atmospheric Sciences Model Studies Finite Volume Coastal Ocean Model for Great
10 South Bay (SoMAS 2016).

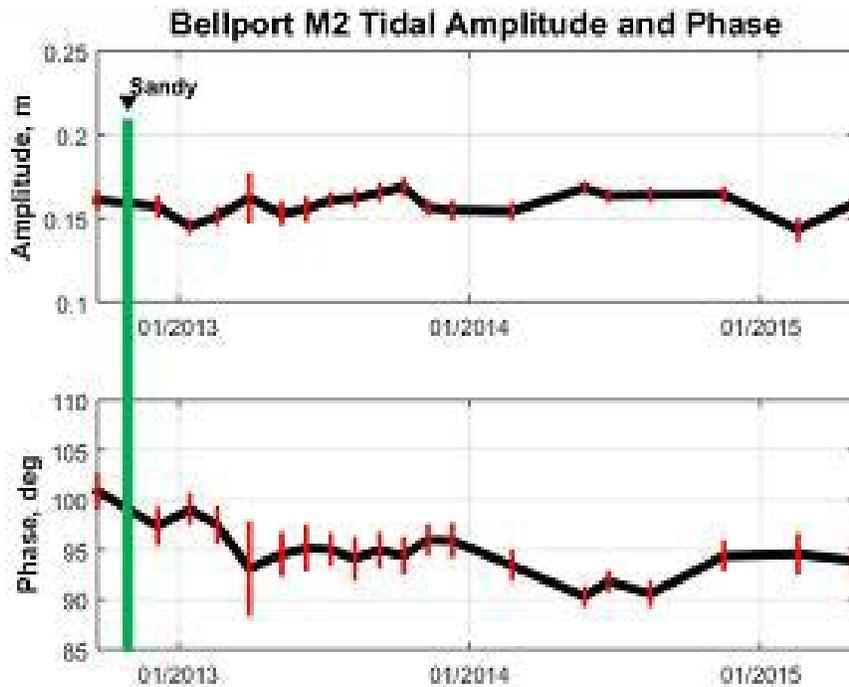

1 Additional FVCOM simulations were conducted on the baseline conditions by adding constant
2 along-bay wind forcing from the west and east. Under west oriented winds with baseline conditions,
3 a large clockwise eddy was created in eastern Great South Bay, with a smaller connected eddy in
4 Bellport Bay. Easterly oriented winds under the no breach baseline condition showed a series of
5 clockwise eddies along the northern side of eastern Great South Bay, and larger counterclockwise
6 eddies on the south side near the barrier beach. Flow was strongly to the east immediately adjacent to
7 the barrier and into Smith Point Channel. The addition of winds to the FVCOM simulations showed
8 the strong influence that wind forces can have on the circulation patterns. In general, westerly
9 oriented winds produce a clockwise eddy while the easterly oriented winds produce a stronger east
10 flowing current in the lower portion of eastern Great South Bay.

11 Impacts of the breach on tide range and residual currents were evaluated with the FVCOM model via
12 tide and wind forced simulations using bathymetry and flood delta morphology surveyed in July
13 2015. These simulations showed the breach to cause a maximum increase in tidal amplitude in the
14 bay of approximately 2.5 centimeters (1.0 inch), very near what has been observed, while also
15 advancing the tidal phase in the eastern bay by about 20 minutes, again very similar to observations.
16 Changes in the general circulation patterns in central and eastern Great South Bay were also seen,
17 with fewer small eddies, and a mean through-flow directed to the west out through Fire Island Inlet
18 (Figure 12). Model simulations with eastward and southward winds showed water levels in the bay to
19 be lower with the breach than without, and under westward and northward winds, the breach
20 simulations produced higher water levels. The eastern portion of the bay (Bellport, Blue Point,
21 Barrett Beach) was shown to be slightly more responsive than the western bay, but the maximum
22 difference in water level for the high wind simulations did not exceed a few centimeters.

23 ***Stony Brook University – School of Marine and Atmospheric Sciences Data Analyses***
24 SoMAS analyzed tide gage records from Bellport and Lindenhurst to evaluate changes in tidal
25 amplitude and phase since before the breach was opened (Flagg et al. 2016). A tidal constituent
26 analysis was performed on data from October 2012 through May 2016 to estimate the primary tidal
27 parameters. Changes in the M2 tidal amplitude and phase for the two stations were compared (Figure
28 13). The data show no significant changes in tidal amplitude at Bellport since before Hurricane
29 Sandy, whereas high tide has advanced by about 15 minutes relative to conditions prior to Hurricane
30 Sandy. At the western end of the bay at Lindenhurst, the amplitude of the M2 tidal constituent has
31 increased by about 2.0 centimeters (0.8 inches) which translates to an increase in tidal range of about
32 4.0 centimeters (1.6 inches). The data do not show a change in tidal phase for this western part of the
33 bay.

1

2

3 **Figure 13.** Temporal variation in the M2 tidal amplitude (in meters) and phase (in degrees) since
 4 Hurricane Sandy at Bellport and Lindenhuert (Flagg et al. 2016).

5 **Summary of Breach Impacts on Water Levels and Circulation**

6 Effects of the breach on high water levels in Great South Bay from daily tidal fluctuations and small
 7 surge events have been evaluated through the use of hydrodynamic modeling and analyses of tide

1 gage data. Both modeled and measured data show a small increase in high tide water levels in the
2 western and central parts of Great South Bay and minimal changes in the eastern parts of the bay.

3 The greatest changes in tidal range are seen near Lindenhurst in western Great South Bay, where
4 modeling and tide gage data indicate high tide water levels have increased between 2.0 and 2.5
5 centimeters (0.8 and 1.0 inches). Elsewhere in central and eastern Great South Bay, increases in the
6 high tide water level as a result of the breach, as shown by modeled and measured data, have been
7 less than 0.8 centimeters (0.3 inches). Daily water levels at the far western end of Great South Bay
8 and Hempstead Bay have not been affected by the breach. Overall, the changes in daily high water
9 levels are small relative to the total water level variations.

10 Stage frequency curves generated from numerical modeling with and without the breach show an
11 increase in the 100-year return period water level (1% annual chance water level) of 60 centimeters
12 (23 inches) for the Connetquot River area in central Great South Bay for the with breach conditions.
13 Elsewhere in Great South Bay and Moriches Bay, the stage frequency curves show increases of 20 to
14 40 centimeters (16 inches) for the 1% annual chance water levels. The stage frequency curves,
15 originally based on model simulations with a breach nearly 2.5 times larger than the current opening,
16 were adjusted using model runs on a breach configuration measured in June 2014. The predicted 1%
17 annual chance water levels are based on statistical analyses of numerical model simulations that may
18 over predict peak storm water levels by as much as 25 centimeters (9.8 inches). Although absolute
19 values of water level increases during storms are difficult to predict with a dynamic coastal system,
20 the order of magnitude spatial distribution of the modeled increases is considered reliable.

21 Numerical model studies and analyses of measured water level data show that the breach has resulted
22 in a phase shift in the tide and surge in the easternmost part of Great South Bay, causing high and
23 low water in Bellport to arrive 20 to 35 minutes sooner as a result of the breach.

24 Hydrodynamic modeling simulations of wider breach scenarios in the wilderness area of 1,128 and
25 1,433 meters (3,701 and 4,701 feet) and 2.1 meters (6.9 feet) depth (6- and 12-month conditions)
26 show a maximum water level increase of 80 centimeters (31 inches) for the 100-year return period
27 event. The breach geometry in these two scenarios is considerably larger than the modeled 3-month
28 condition and the June 2014 breach, and as such, the model results may be more representative of
29 future storm water levels under climate change and sea level rise conditions.

30 Hydrodynamic modeling indicates that the breach has altered the general circulation patterns in
31 central and eastern Great South Bay. Prior to the breach the circulation was characterized by a
32 number of smaller localized eddies. Since the breach the circulation has become a mean through-flow
33 directed from Bellport Bay to the west out through Fire Island inlet. This change in residual
34 circulation suggests a reduction in residence time in eastern Great South Bay which is an important
35 factor that affects bay water quality.

36

1 **Water Quality**

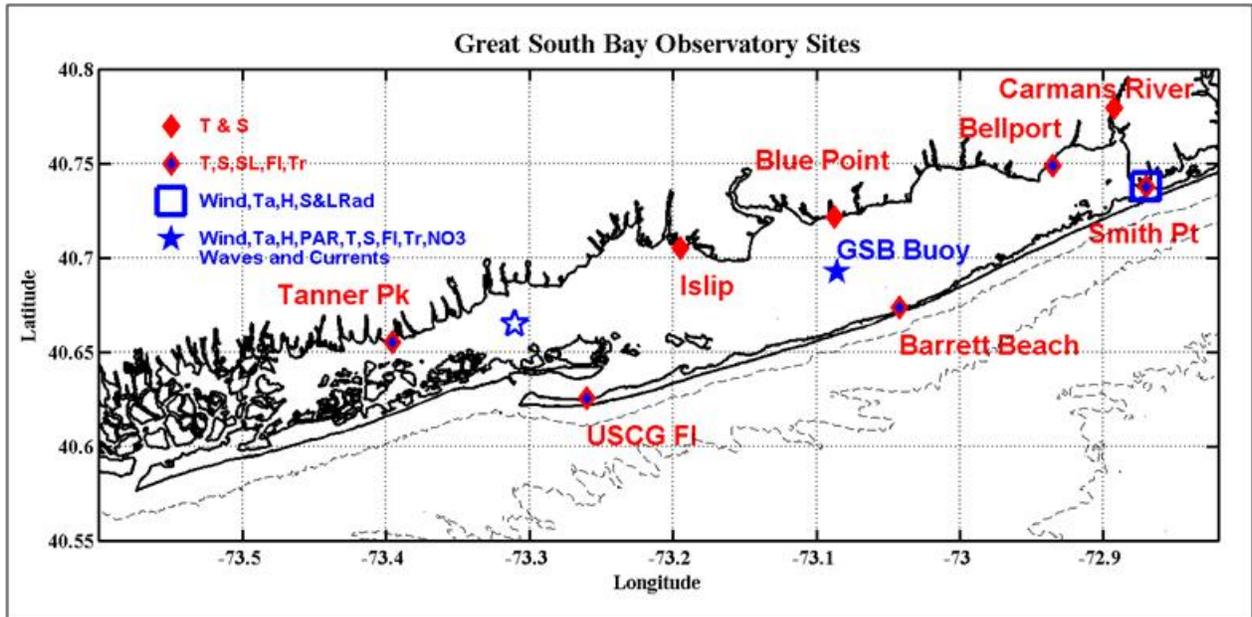

2 Water quality in Great South Bay is influenced by mixing between fresh and marine waters through
3 the tidal inlets. The wilderness breach in Fire Island has the potential to change bay water quality by
4 increasing tidal and subtidal flushing. Increased tidal and subtidal flushing can lead to water quality
5 improvements by reducing residence times for water parcels in the bay, which has a history of
6 impaired ecological function.

7 Key estuarine water quality parameters such as temperature and salinity are partially controlled by
8 the extent of tidal and subtidal flushing, and these parameters are important factors that influence the
9 bay ecology. Water temperature is a driving factor in the physiochemical and biological processes
10 that determine how well the estuary can support aquatic life. Variations in salinity according to
11 location in the bay, tidal fluctuations, and volumes of freshwater input influence the distributions of
12 estuarine species.

13 For the purposes of this technical report, the discussion of water quality within the Great South Bay
14 and Moriches System will focus primarily on the physical characteristics of residence time,
15 temperature, and salinity that impact water quality. Additional water quality parameters relating to
16 nutrients, chlorophyll a, bacteria, and certain suspended algal communities are discussed in the
17 marine and estuarine resources technical report.

18 **Synthesis of Water Quality Pre versus Post Breach**

19 Water quality monitoring in Great South Bay has been conducted by Suffolk County and Stony
20 Brook University's SoMAS. Combined, these datasets cover an extensive period before Hurricane
21 Sandy, and therefore offer excellent sources of information to evaluate impacts of the breach on
22 water quality. Suffolk County monitoring of Great South Bay began in 1976 and includes regular
23 sampling throughout the bay for various physical parameters including salinity and temperature.
24 SoMAS has maintained a network of observation stations in the bay since 2005, measuring a full
25 suite of physical parameters for tracking water quality and meteorological conditions (Figure 14).
26 More recent studies since formation of the breach looking at the plankton community in Great South
27 Bay have used water quality parameters from the SoMAS observation stations as well as cruise data
28 to evaluate effects of the breach on temperature and salinity (Gobler, Collier, and Lonsdale 2014).
29 Residence times in Great South Bay have been calculated using salinity and freshwater input data,
30 and more recently SoMAS modeled residence times using the FVCOM model. A brief summary of
31 findings and conclusions regarding impacts of the breach on water temperature, salinity, and
32 residence time is provided below.

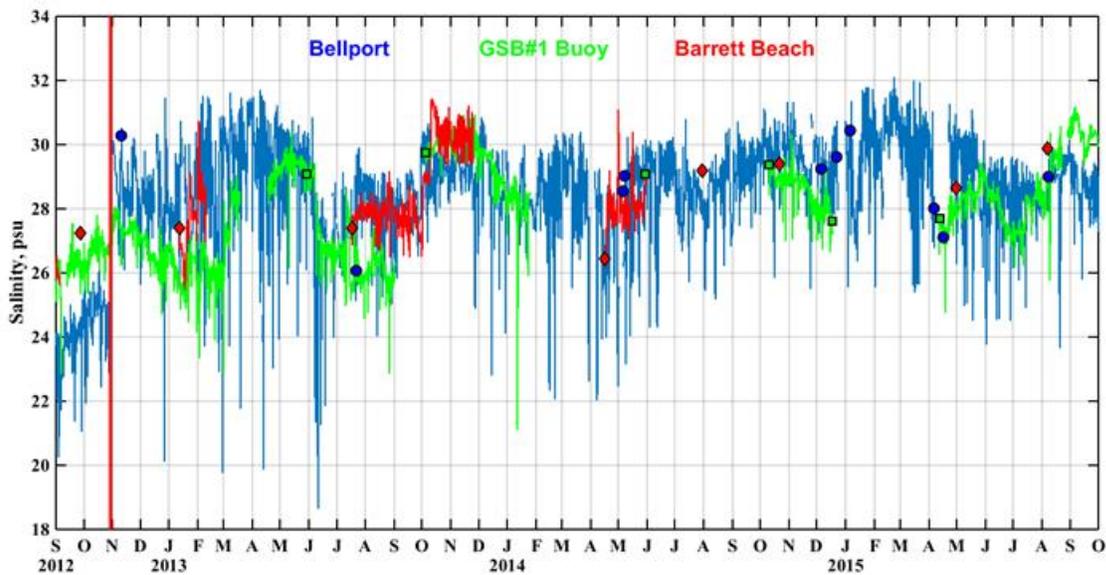

1
 2 **Figure 14.** Great South Bay observatory locations maintained by School of Marine and Atmospheric
 3 Sciences Model Studies (SoMAS 2016).

4 Residence times for Great South Bay before the wilderness breach were calculated for the NPS by
 5 Hinga (2005). The volume of freshwater in the estuary, taken as the difference between ocean and
 6 bay salinities, was divided by the rate of freshwater input to determine an average residence time of
 7 50 days. Using somewhat different assumptions for the dimensions of Great South Bay, an average
 8 residence time of 96 days was calculated by Conley (2000) prior to the breach. Predictions on
 9 potential changes in residence time with a breach at Old Inlet showed a reduction to 40 days (Conley
 10 2000). This estimate suggests that flushing characteristics in Great South Bay would be enhanced by
 11 the breach. However, it was noted that flushing would not be uniform across the bay, with potential
 12 residence times considerably greater in the northern portions of the bay near the mainland and lower
 13 in the southern reaches. More recent calculations of residence time conducted by SoMAS for the
 14 Bellport Bay area near the wilderness breach showed a decrease from 25 to 10 days (Gurdon et al.
 15 2015; Flagg pers. comm. 2016).

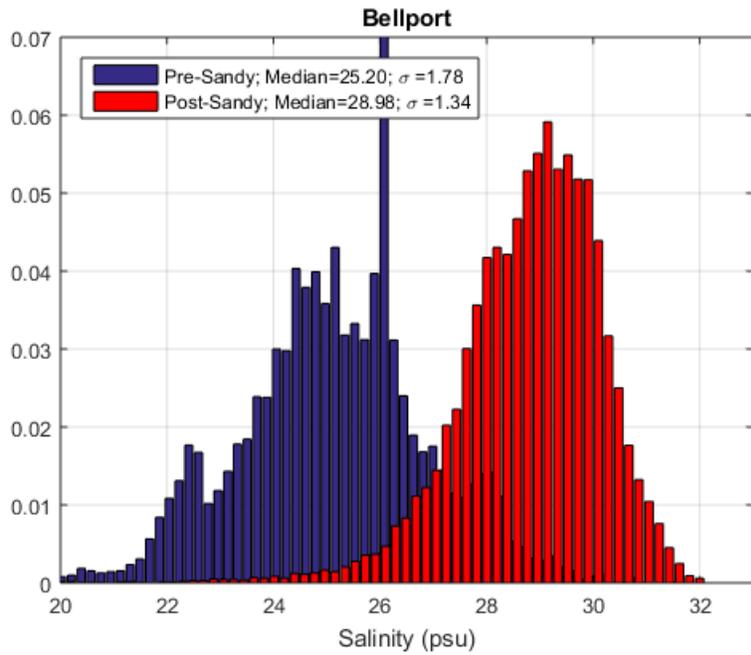

16 Water temperatures in Great South Bay vary seasonally. Synthesis of Suffolk County data before the
 17 breach showed summer surface water temperatures of 25 to 26°C, with occasional measurements up
 18 to 29°C. Wintertime data were not collected as regularly, but temperatures of 0 to 2°C were common
 19 (Hinga 2005). These values are consistent with pre-breach water temperatures measured at the
 20 SoMAS observation stations (SoMAS 2016). Comparison with data collected after the breach shows
 21 that summer temperatures are somewhat cooler, while winter temperatures do not seem to be
 22 impacted by the breach. More specifically, Goble, Collier, and Lonsdale (2014) found a decrease in
 23 summer temperatures in Bellport Bay, Narrow Bay, and Moriches Bay by as much as 3°C. Despite
 24 findings that the breach has resulted in a small decrease in summertime water temperatures, in
 25 general, water temperatures in Great South Bay are mostly dependent on air-sea interactions rather

1 than bay-ocean exchange. Changes in the heat budget of the bay due to additional water exchange
2 through the breach are planned by SoMAS for future hydrodynamic model experiments.

3 Salinities in the bay are greatly influenced by the influx of groundwater, rainfall, wind stress, and
4 location. Areas closest to the inlets have the highest salinities and areas along the northern shoreline
5 closest to streams and areas of groundwater influx have the lowest salinities. In general, salinities are
6 the lowest in the northeast and north central areas of the bay, and increase toward the western end of
7 the bay and Fire Island Inlet. Before formation of the wilderness breach, average salinities typically
8 ranged from 25 to 30 practical salinity units (psu) (Hinga 2005), except near Bellport where values
9 were lower: between 20 and 25 psu. Since formation of the breach, average salinities in the eastern
10 half of the bay have increased. Data collected by SoMAS at Bellport and the Great South Bay #1
11 buoy show a sharp increase in salinity at both stations following the breach (Figure 15; Flagg pers.
12 comm. 2016). Bellport Bay has seen the greatest increase in average salinity since the breach
13 (+5 psu). Barrett Beach on Fire Island to the west of the breach has seen an increase of +2 psu and
14 measurements from the US Coast Guard Station at Fire Island Inlet show a negligible change in
15 salinity since the breach (Figure 16 a-c; Flagg pers. comm. 2016).

4 Fire Island Inlet following formation of the wilderness breach (Flagg pers. comm. 2016 (provided at
5 workshop)). Each figure shows the frequency distribution of salinity pre-Sandy and post-Sandy.

6 **Summary of Breach Impacts on Residence Time, Temperature, and Salinity**

7 Effects of the breach on key water quality parameters have been evaluated through the use of
8 numerical modeling and analyses of long-term water quality data measured at various locations in the
9 bay. In general, water quality in the bay has improved since formation of the breach.

10 Residence time for Great South Bay prior to the breach was calculated to be 50 to 100 days.
11 Predictions on potential changes in residence time with a breach at Old Inlet showed a reduction to
12 40 days. Long-term observations suggest a reduction in residence time calculated based on a
13 freshwater fraction method from 25 to 10 days locally for the Bellport Bay area.

14 Data analyses on water temperature changes since the breach indicate a reduction by as much as 3°C
15 during the summer months in Bellport Bay, Narrow Bay, and Moriches Bay. However, water
16 temperatures in Great South Bay are mostly dependent on air-sea interactions and to a lesser extent
17 on water exchange through the breach. Hydrodynamic modeling is planned to further evaluate the
18 influence of additional water exchange through the breach on the heat budget of the bay. Salinities in
19 Great South Bay have increased by 2 psu in the eastern central portion of the bay, and by as much at
20 5 psu in the Bellport area.

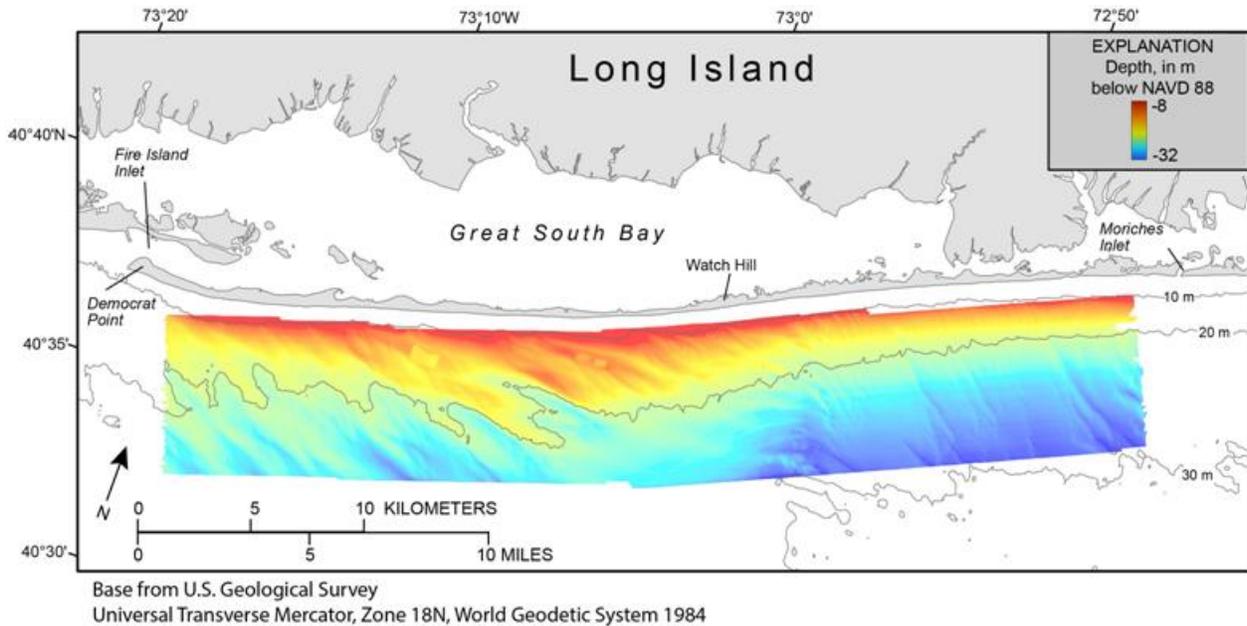

1 **Waves**

2 Tidal inlets through barrier beaches can alter wave action along the outer coastline and can also allow
3 the transmission of increased wave energy through the inlet into more sheltered back bay areas. The
4 propagation and breaking of incident waves along the outer coastline is affected by the morphology
5 of the ebb-tidal shoals and the strength and structure of the ebbing currents. For example, wave
6 refraction over and around the ebb-tidal shoals can generate currents that flow back toward the inlet
7 along the adjacent shorelines, particularly on the downdrift side of the inlet. This process can result
8 in erosion, especially at inlets with large ebb shoal complexes. Ocean waves entering an inlet against
9 the ebb current tend to steepen as their wave heights increase and wavelengths decrease. This wave
10 current interaction can influence channel shoaling and pose a threat to navigation. In cases where
11 tidal inlets are wide and deep enough to allow the propagation of wave energy through to the
12 estuarine environment, the increased energy can cause shoreline erosion and changes in
13 sedimentation. Potential impacts of the wilderness breach on outer coast and bay area wave
14 conditions are described in the following section.

15 **Synthesis of Wave Information Pre versus Post Breach**

16 The wave climatology offshore of Long Island is characterized by moderate Atlantic waves typically
17 from the southeast quadrant. There is a relatively strong seasonal component of mild waves during
18 summer, severe waves associated with extratropical storms frequent during winter and spring, and
19 severe waves associated with tropical storms during fall. Mean significant wave height over a 6-year
20 period at NOAA National Data Buoy Center Buoy #44017 is approximately 1.5 meters (4.9 feet)
21 with a mean wave period of 5 seconds (NOAA 2016). Nearshore waves approaching the shoreline
22 are substantially reduced in energy as waves shoal across the shelf. The majority of waves are from
23 the southeast and the more severe storms associated with extratropical storms are from the east-
24 southeast. This results in a net westerly longshore transport direction (Leatherman 1985; Smith et al.
25 1999).

26 The inner shelf at the eastern end of the Fire Island (east of Watch Hill) is characterized by relatively
27 straight and parallel contours (Figure 17; Schwab, Denny, Baldwin 2014a). This means that the
28 bathymetric contours are parallel with the shoreline, forming a uniformly sloping shelf. The
29 consistent nature of the bathymetry causes the incident waves to act uniformly across the inner shelf.
30 As waves approach the nearshore area and enter the surf zone, they interact with the nearshore bar
31 and this causes variations in wave energy along the shoreline (Nelson et al. in review). Since
32 formation of the wilderness breach, the ebb-tidal delta has caused a perturbation in the nearshore bar
33 system.

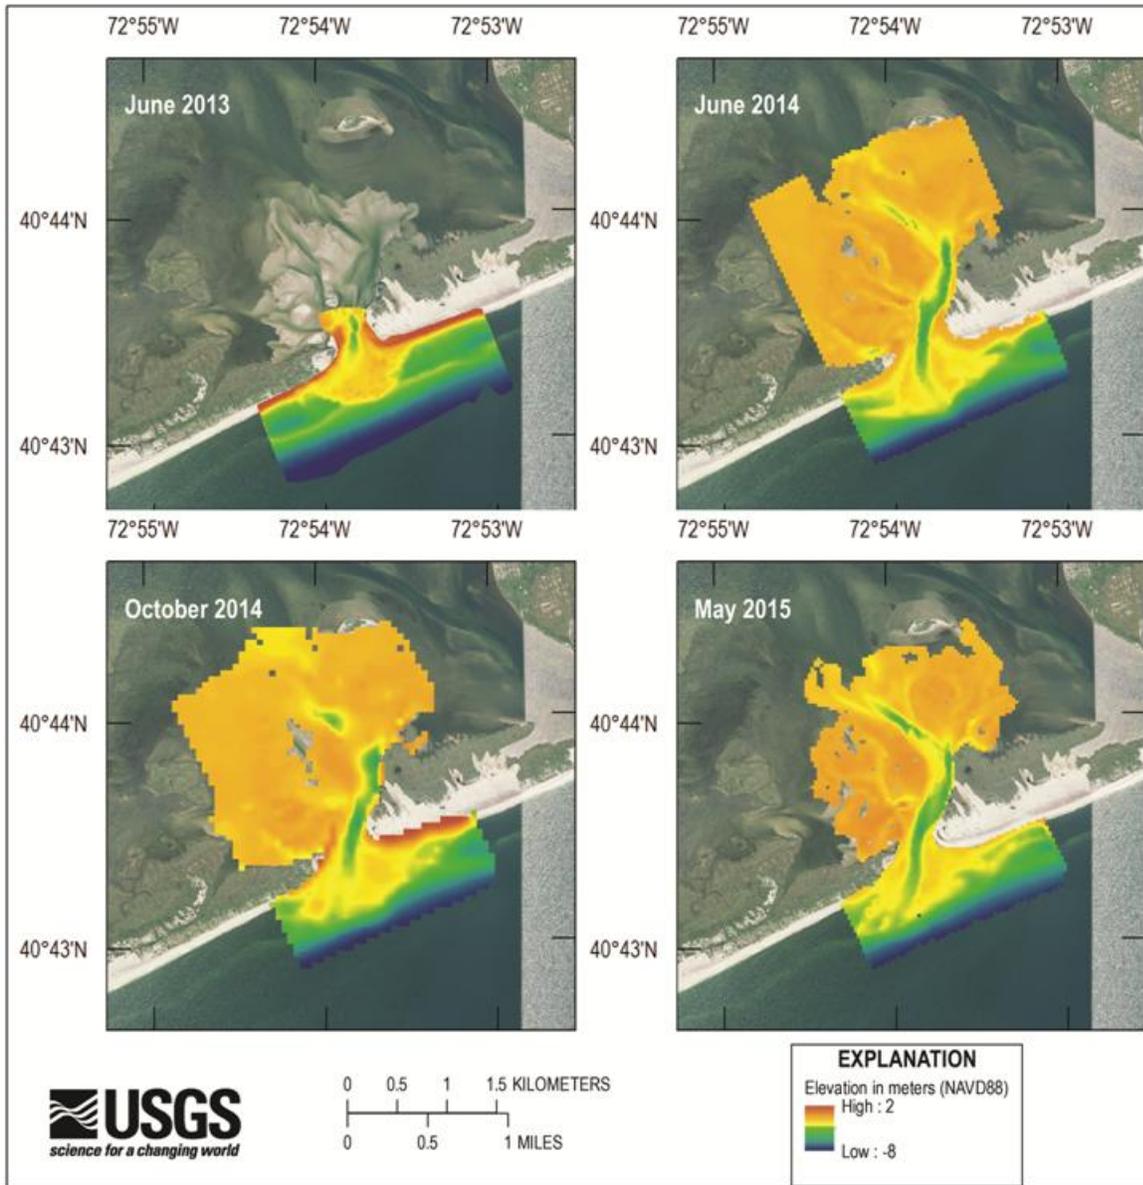

1
2
3 **Figure 17.** US Geological Survey bathymetric map shore-connected ridges along the western end of Fire
4 Island and a more planar shelf with straight and parallel contours on the eastern end.

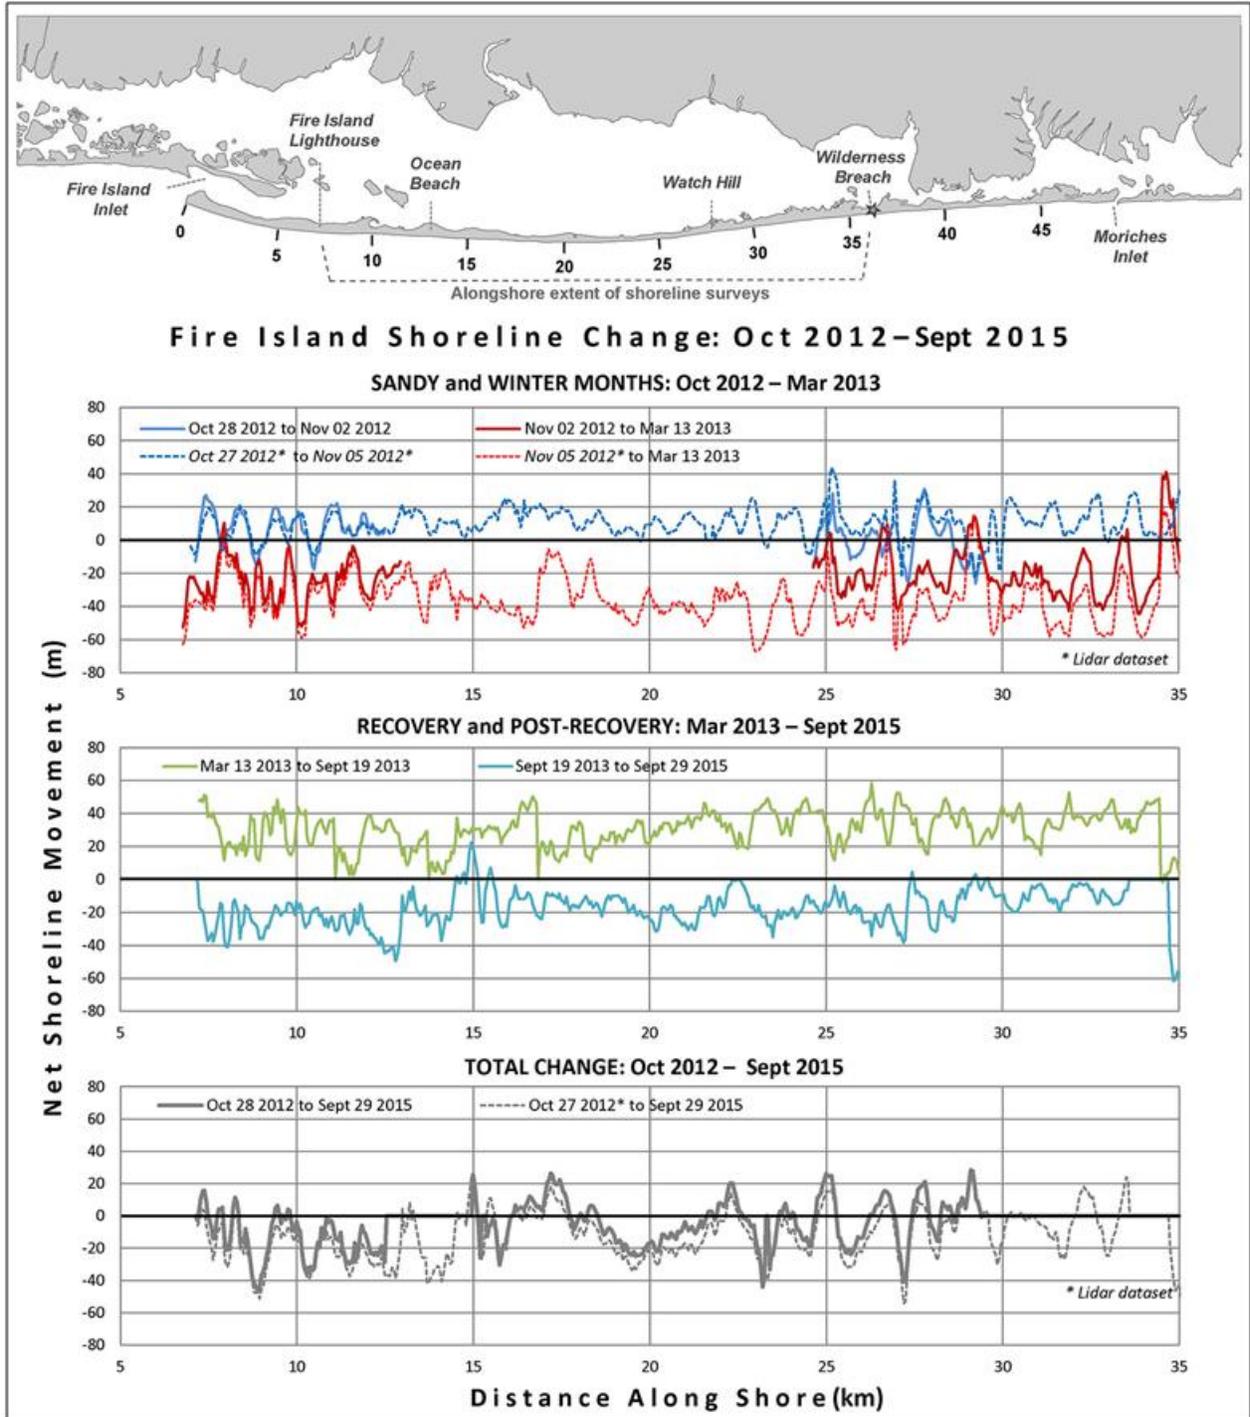

5 Studies specifically looking at impacts of the breach on the nearshore wave climatology have not
6 been conducted. The USACE and Deltares model studies have simulated wave conditions in the
7 breach; however, the results have not been extracted at the fine resolution needed to evaluate
8 localized wave changes and resulting impacts on sediment transport. Data collected to date suggests
9 that shoreline erosion resulting from wave interaction with the ebb-tidal shoals is small and localized
10 to the downdrift or western side of the inlet within the wilderness area. Supporting evidence includes
11 a relatively small ebb shoal complex and evidence of localized downdrift increased shoreline erosion
12 since formation of the breach.

13 The USGS collected bathymetric surveys of the breach and associated flood and ebb shoals in June
14 2013, June 2014, October 2014, and May 2015 (Figure 18; Brownell et al. 2015; Nelson et al. 2016a,
15 2016b; and Nelson et al. in review). These surveys show a significant increase in the size of the ebb
16 shoal between June 2013 and June 2014, followed by relatively little growth through October 2014.
17 This suggests that ebb delta growth has slowed. Current photographs show the delta to extend
18 approximately 0.8 kilometer (0.5 mile) on either side of the breach centerline. Shoreline change data
19 analyzed by the USGS for the period October 2012 to September 2015 show effects of the breach to
20 be localized to an area approximately 0.5 kilometer (0.3 mile) downdrift of the opening (Figure 19;
21 USGS 2016a). Since September 2013 the shoreline immediately downdrift of the breach has eroded
22 approximately 60 meters (197 feet). This is in sharp contrast to shorelines further to the west that
23 have eroded between 20 and 30 meters (66 and 98 feet). The relatively small size of the ebb delta and
24 lack of recent growth, in combination with localized downdrift erosion were cited as evidence that
25 the breach has a limited impact on the adjacent open coast shorelines. It was not determined whether

1 the localized downdrift erosion was entirely due to wave interaction with the ebb shoal; however, it
2 was concluded that changes in the nearshore waves as a result of the breach are not likely to result in
3 erosion much beyond the opening. Therefore, developed areas on Fire Island west of the breach will
4 not be affected by changes in wave climatology due to the breach.

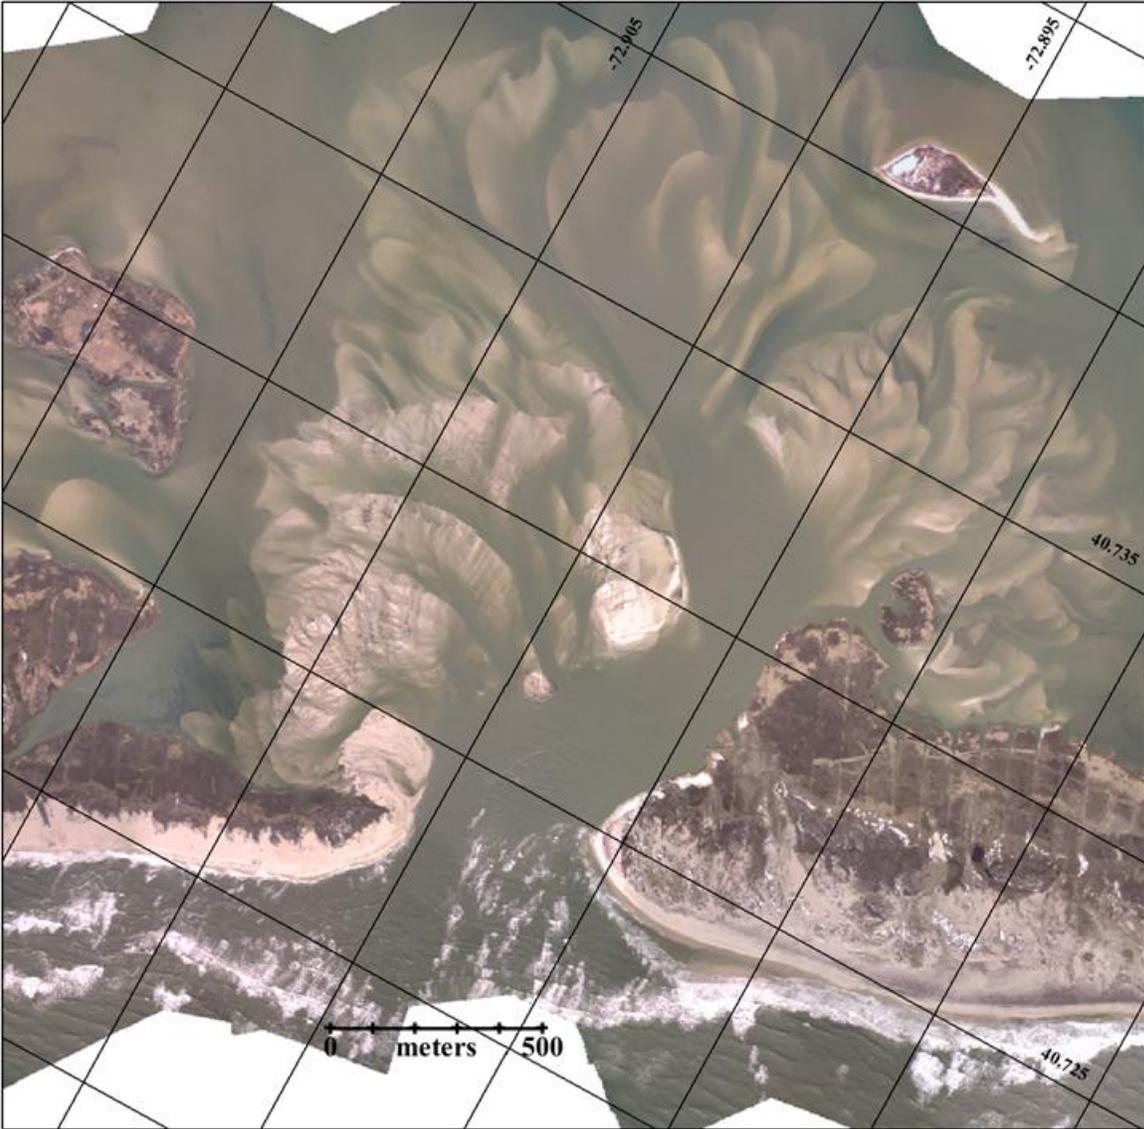

5
6 **Figure 18.** US Geological Survey bathymetric surveys of the breach and associated shoals from June
7 2013, June 2014, and October 2014 (Brownell et al. 2015; Nelson et al. 2016a and 2016b).

1
 2 **Figure 19.** US Geological Survey shoreline change data in the Fire Island National Seashore for the
 3 period October 2012 to September 2015 (USGS 2016a).
 4 The width of the breach and shallow nature of the flood tidal delta are primary factors that limit wave
 5 propagation from the open ocean through the breach to Great South Bay. Specific studies have not
 6 been conducted to evaluate this process, but general consensus at the January workshop was that

1 wave activity in the bay has not increased as a result of the breach. The current width of the breach at
2 approximately 500 meters (1,640 feet) provides a narrow window of exposure for Great South Bay
3 (Figure 16; SoMAS 2016), and any waves that enter the breach will be broken by the shallower
4 waters over the flood tidal delta (Figure 20). The potential for increased wave activity in Great South
5 Bay given a wider breach was also considered to be low, since the extent and shallow nature of the
6 flood shoals will provide protection. Based on these discussions, it was concluded that the potential
7 for increased shoreline erosion in Great South Bay as a result of wave propagation through the beach
8 was extremely low.

9
10 **Figure 20.** Jan. 31, 2016 aerial photo showing the configuration of the breach and the approximate width
11 of 500 meters (1,640 feet) (SoMAS 2016).

1 **Summary of Breach Impacts on Waves**

2 Impacts to waves along the south shore of Fire Island as a result of the breach are localized to an area
3 within 0.5 to 1.0 kilometer (0.3 to 0.6 mile) of the breach. Wave interaction with the ebb shoals may
4 be partly responsible for increased shoreline erosion within an area 0.5 kilometer (0.3 mile)
5 downdrift of the breach.

6 Wave propagation from the ocean through the breach and into Great South Bay is limited by the
7 width of the breach and the shallow nature of the flood tidal delta complex. Consequently, the
8 potential for increased shoreline erosion in the bay as a result of wave propagation through the
9 breach is extremely low.

10

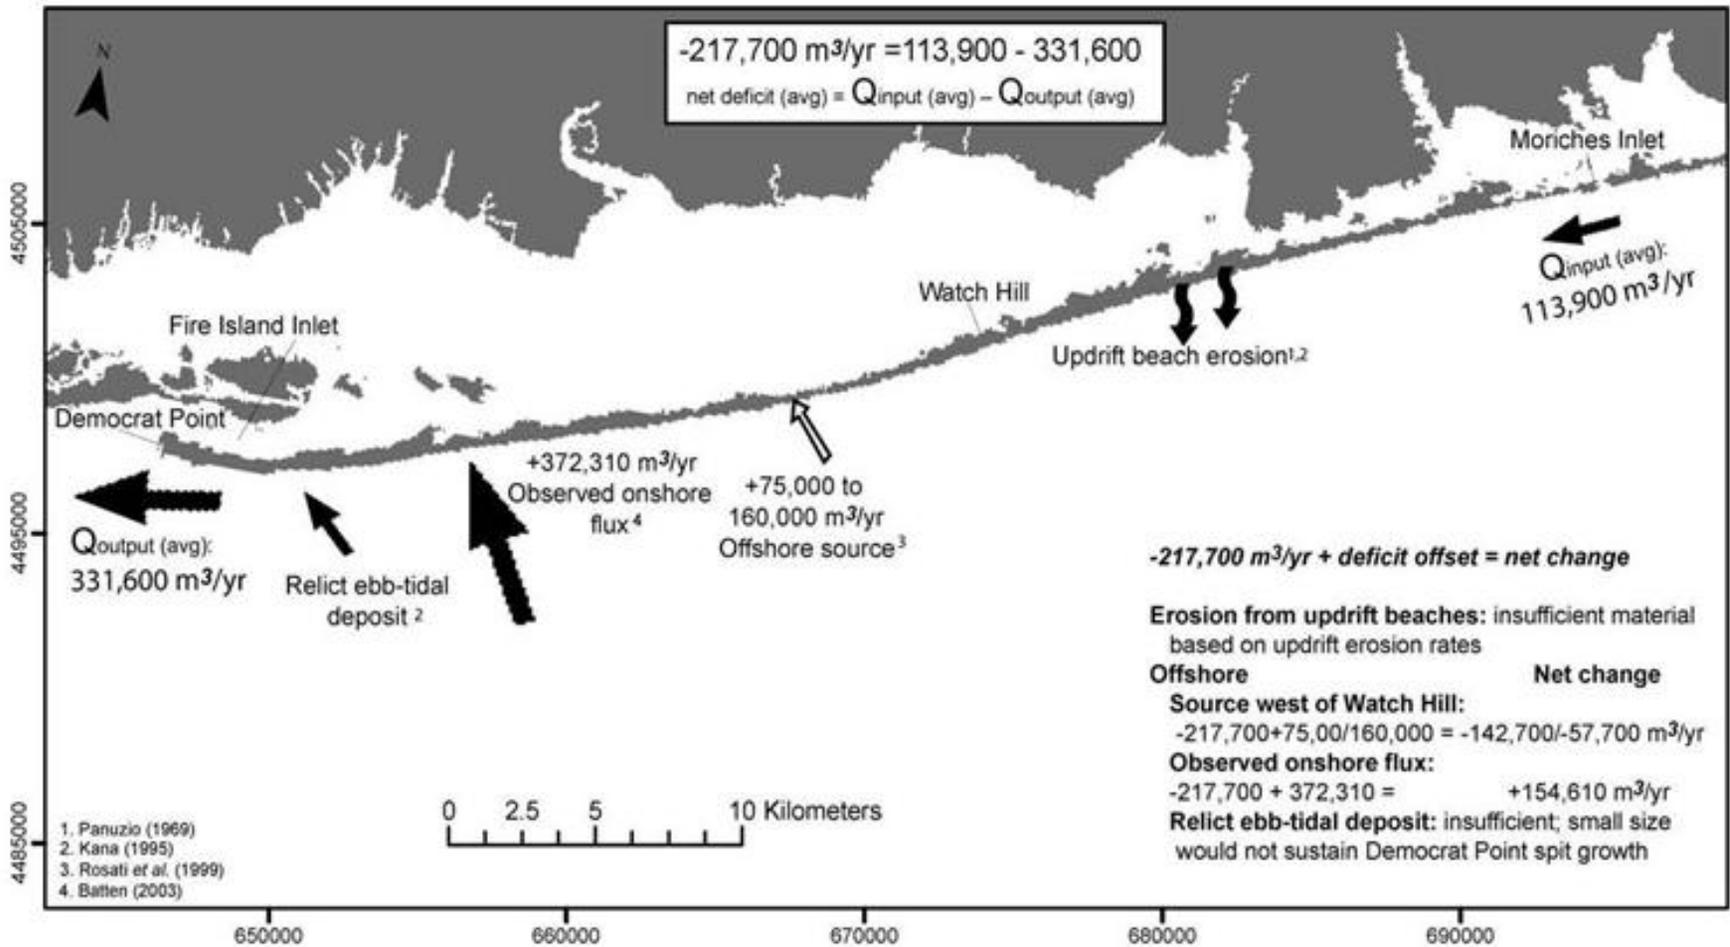

1 **Sediment Transport and Breach Geomorphology**

2 Sediment transport processes along open coast shorelines are often interrupted by tidal inlets. Inlets
3 provide conduits for the transport of littoral drift into flood and ebb shoal complexes, back barrier
4 bays, and salt marsh systems. Inlets that remove material from the longshore transport system are
5 sediment sinks. In cases where a significant percentage of the annual littoral drift is lost through
6 landward transport into the inlet, erosion of the downdrift shorelines can be an issue. Inlets that are
7 not sediment sinks typically allow sediment bypassing through one or more mechanisms that help to
8 feed the downdrift shorelines with sediment. The geomorphology of inlet systems is therefore
9 influenced by sediment transport processes that are driven by a combination of waves and tidal
10 currents. Potential impacts of the wilderness beach on sediment transport processes are described in
11 the following section. Changes in breach geomorphology are also discussed.

12 **Synthesis of Sediment Transport and Geomorphology Information Pre versus Post** 13 **Breach**

14 The dominant direction of longshore transport from east to west along Fire Island has been
15 documented based on spit growth and inlet dredging records (Leatherman 1985; Kana 1995; Smith et
16 al. 1999). Rates of longshore sediment transport have been estimated based on calculations at
17 Moriches and Fire Island Inlets. Most studies have found higher rates of transport leaving from Fire
18 Island Inlet than entering at Moriches Inlet, suggesting that additional sand is added to the overall
19 budget somewhere along Fire Island (Panuzio 1969; Kana 1995; Rosati et al. 1999). Hapke et al.
20 (2010) reviewed published sediment budgets for the area and found an average increase of 217,000
21 cubic meters (7,663,283 cubic feet) per year in the transport rates between Moriches and Fire Island
22 Inlets. Updrift shoreline erosion and redistribution of beach nourishment material have been cited as
23 potential sources for the additional sediment. Shoreface-connected sand ridges have also been
24 proposed as a possible source of sediment required to balance the sediment budget (Schwab et al.
25 2000). These are linear shoals that tend to be oriented parallel to the direction of the dominant storm
26 wave approach. More recent work suggests the source of sediment is from erosion of the inner shelf
27 with the sand ridges and beach both composed of the reworked shelf material (Schwab et al. 2013;
28 Schwab et al. 2014b). Warner et al. 2014 use modeling results to suggest the net onshore flux is from
29 the troughs between the sand ridges. Hapke et al (2010) used previously published sediment budgets
30 to develop a single conceptual model to balance existing sediment budget estimates for Fire Island by
31 considering these onshore sediment transport contributions. The conceptual model shows that
32 onshore sediment transport via the shoreface-connected ridges is an important process along the
33 western end of Fire Island, some 16 kilometers (9.9 miles) west of the wilderness breach (Figure 21).
34 Longshore transport rates in the vicinity of the wilderness breach are likely similar to those estimated
35 as influx at Moriches Inlet.

1

2

3 **Figure 21.** Conceptual model to balance the Fire Island sediment budget between Moriches and Fire Island Inlets (Hapke et al. 2010 and
4 references therein).

1

2 There have been no updates to the Fire Island sediment budget since formation of the wilderness
3 breach; although existing data suggest that the inlet is not causing a significant interruption in
4 longshore sediment transport. Supporting data include analyses of shoreline change downdrift of the
5 breach following Hurricane Sandy (Henderson et al. 2015), analyses of flood shoal growth, and
6 evaluation of ebb delta breaching processes.

7 Beach surveys have been conducted by the USGS to evaluate shoreline changes caused by Hurricane
8 Sandy and to monitor the continued response and recovery of the barrier beach (USGS 2016a).
9 Surveys have been collected along shore parallel and shore normal tracks to capture the base of the
10 dune, the mid-beach, and the upper and lower foreshore along the length of Fire Island west of the
11 wilderness breach. The dataset includes measurements before and after Hurricane Sandy, monthly
12 data between December 2012 and April 2013, and a September 2015 survey. LiDAR data have also
13 been used to supplement the USGS field measurements. Plots of net shoreline movement (shown in
14 Figure 19) were developed to show various stages of shoreline response, where the wilderness breach
15 is located at the far right of the x-axis (USGS 2016a). Data from the winter months following
16 Hurricane Sandy showed significant erosion along most of the shoreline (November 2012 to March
17 2013; red line top plot). A 6-month recovery period was then identified during which time the
18 shoreline accreted an average of 30 meters (98 feet) (March 2013 to September 2013; green line
19 middle plot). Over the next two years the system transitioned to a state of increased or sustained
20 erosion with an average change of -17 meters (-56 feet) (September 2013 to September 2015; blue
21 line middle plot). The average net shoreline movement from immediately before Hurricane Sandy to
22 the most recent September 2015 survey was erosional, with an average movement of -12 meters (-39
23 feet) (bottom plot). While the net shoreline response shows distinct zones of erosion and accretion
24 along the length of Fire Island, there is no indication that the wilderness breach is creating a
25 regionalized downdrift zone of erosion caused by trapping of the littoral drift. As discussed
26 previously, the breach appears to be responsible for localized erosion immediately downdrift of the
27 opening, but there is no indication that this erosion extends more than 1 kilometer (0.6 mile) west of
28 the breach.

29 Bathymetric and topographic surveys of the wilderness beach and associated shoals have also been
30 used by the USGS and Deltares to track changes in the morphology of the system. Analyses using
31 these data suggest that the breach is not currently acting as a sediment sink, and therefore not causing
32 a major interruption in littoral drift. A total of four surveys were collected in June 2013, June 2014,
33 October 2014, and May 2015 using a combination of the USACE Lighter Amphibious Resupply
34 Cargo and USGS personal watercraft equipped with a backpack GPS unit (Nelson et al. 2016a).
35 Flood shoals that formed inside Great South Bay as a result of the breach showed fast initial growth
36 in the first winter after Hurricane Sandy, importing large amounts of sediment from erosion of the
37 adjacent barriers. During this initial period the breach acted as a sediment sink. Following the winter
38 of 2013, growth of the flood shoals stabilized and the system is reported by Deltares to be exporting
39 sediment (Deltares 2016). Volumetric change analyses on bathymetric data from the flood delta
40 suggests that the increased size of the delta seen in aerial photographs may be the result of reworking

1 of deposits and addition of sediment derived from channel deepening rather than the import of
2 sediment from the ocean side of the system (van Ormondt pers. comm. 2016).

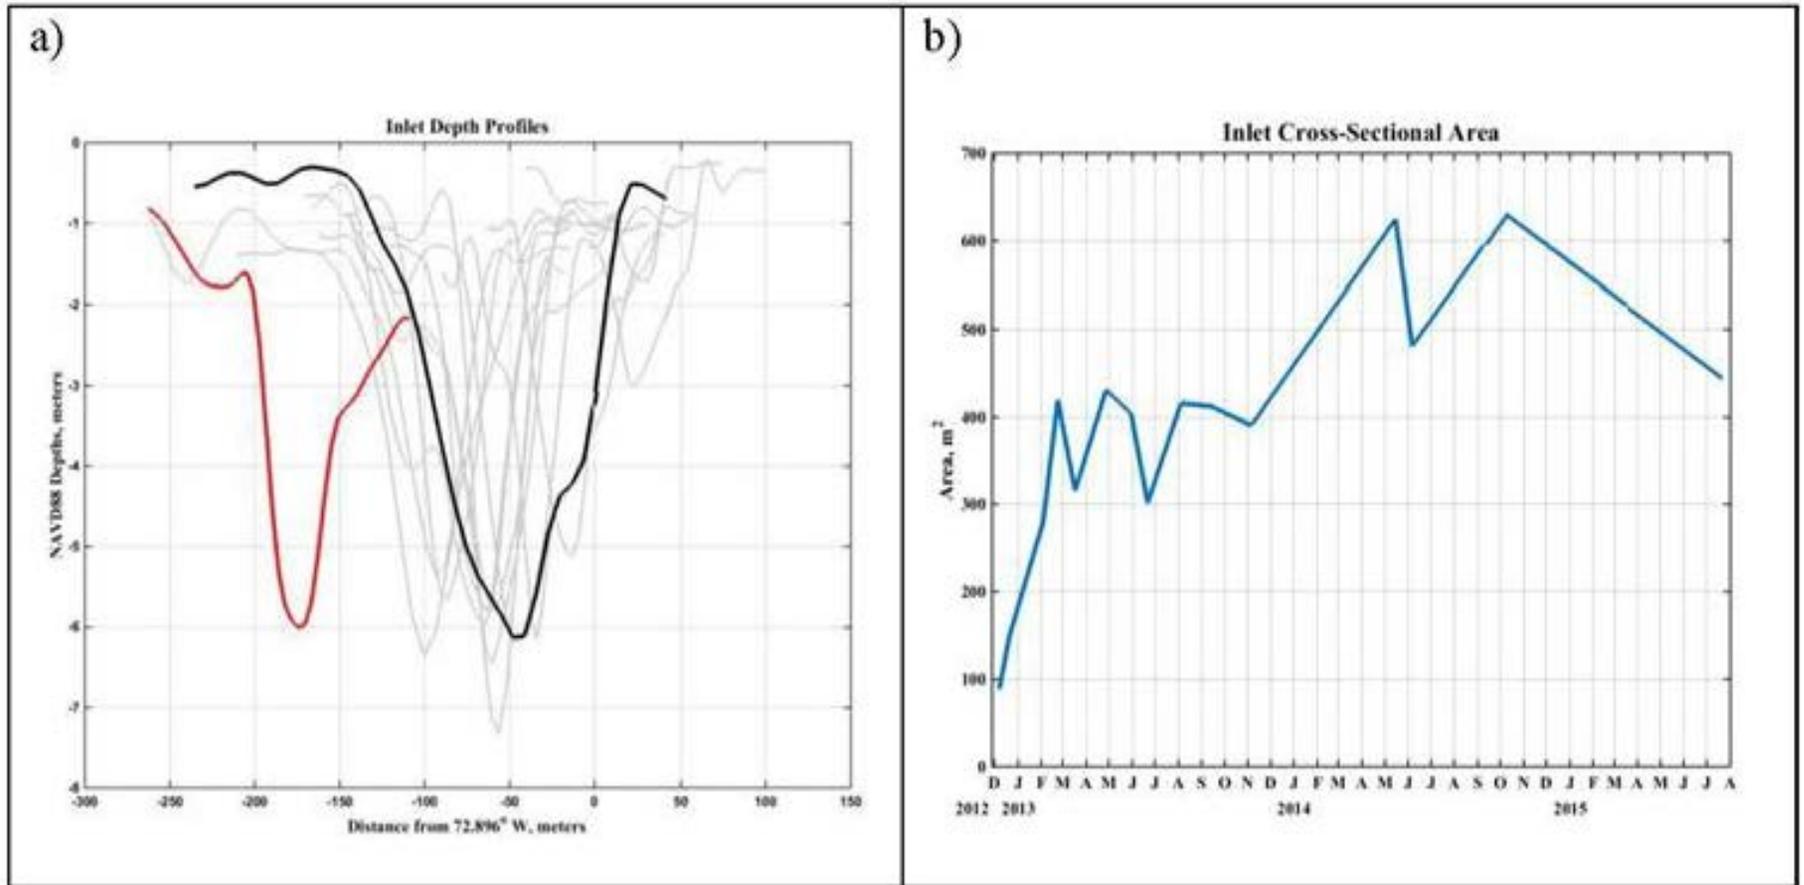

3 Review of aerial photographs provides further support that the breach is relatively efficient at
4 bypassing sediment to the downdrift shoreline. Continuous bypassing around the outer edge of the
5 ebb shoal driven by waves and currents is a mechanism for transport around the breach. This method
6 delivers sediment to the western shoreline approximately 1.0 kilometer (0.6 mile) downdrift of the
7 breach where the ebb shoal merges with the nearshore bathymetry. Sediment is also transported via
8 shallow channels into the main breach channel from the east and moves out to the west through ebb
9 shoal channels, resulting in negligible net influx to the flood shoal complex. The migration of large
10 bar complexes to the downdrift side of the breach also bypasses sediment, as the main channel
11 switches from a northeast-southwest orientation through the ebb shoal to a more direct north-south
12 orientation, usually initiated by a storm.

13 Changes in the geomorphology of the wilderness breach have been documented by SoMAS (2016)
14 and the USGS (Nelson et al. 2016b; Nelson et al. in review) using surveys of the breach cross-
15 sectional area, width, depth, and location. The geomorphologic parameters fluctuated along with the
16 patterns of erosion and deposition since the breach opened. Generally the breach widened and the
17 cross-sectional area increased during the first 2 years after the breach formed, then decreased during
18 the third year, 2015.

19 Flagg et al. (2015) and Flagg and Flood (2013) describe the changes in breach cross-sectional area
20 and nearby features based on bathymetric surveys conducted between December 2012 and August
21 2015. These data show that the cross-section increased during the first 2 years after the breach
22 formed, then decreased somewhat during 2015. Figure 22 shows the spatial patterns and extent of
23 change. Figure 22a (left panel) shows variations in the cross-sectional profile (width, depth, and
24 location) over time and Figure 22b (right panel) shows changes in the breach cross-sectional area
25 since December 2012. The inlet depth profiles show maximum depths have ranged from 3 to 7.5
26 meters (10 to 25 feet) NAVD88 and the location of the breach centerline has migrated approximately
27 200 meters (656 feet) to the west since initial formation. The cross-sectional area increased from
28 about 100 square meters (1,076 square feet) in 2012 to about 300–400 square meters (3,229–4,306
29 square feet) during 2013, further increased to about 500–600 square meters (5,382–6,458 square feet)
30 in 2014, and then decreased steadily during 2015. The most recent data (July 2015) from Flagg et al.
31 (2015) indicate the cross-sectional area is about 450 square meters (4,844 square feet).

32 Additional cross-sectional data are available from the June 2013, June 2014, October 2014, and May
33 2015 surveys collected by the USGS (Brownell et al. 2015; Nelson et al. 2016a, 2016b; and Nelson
34 et al. in review). These survey data corroborate the trends seen in the SoMAS data (Figure 22, right
35 panel). Combination of the two data sets creates a more robust series that could be updated in the
36 future with regular measurements of cross-section to identify changes in breach morphology
37 indicative of widening.

1
2

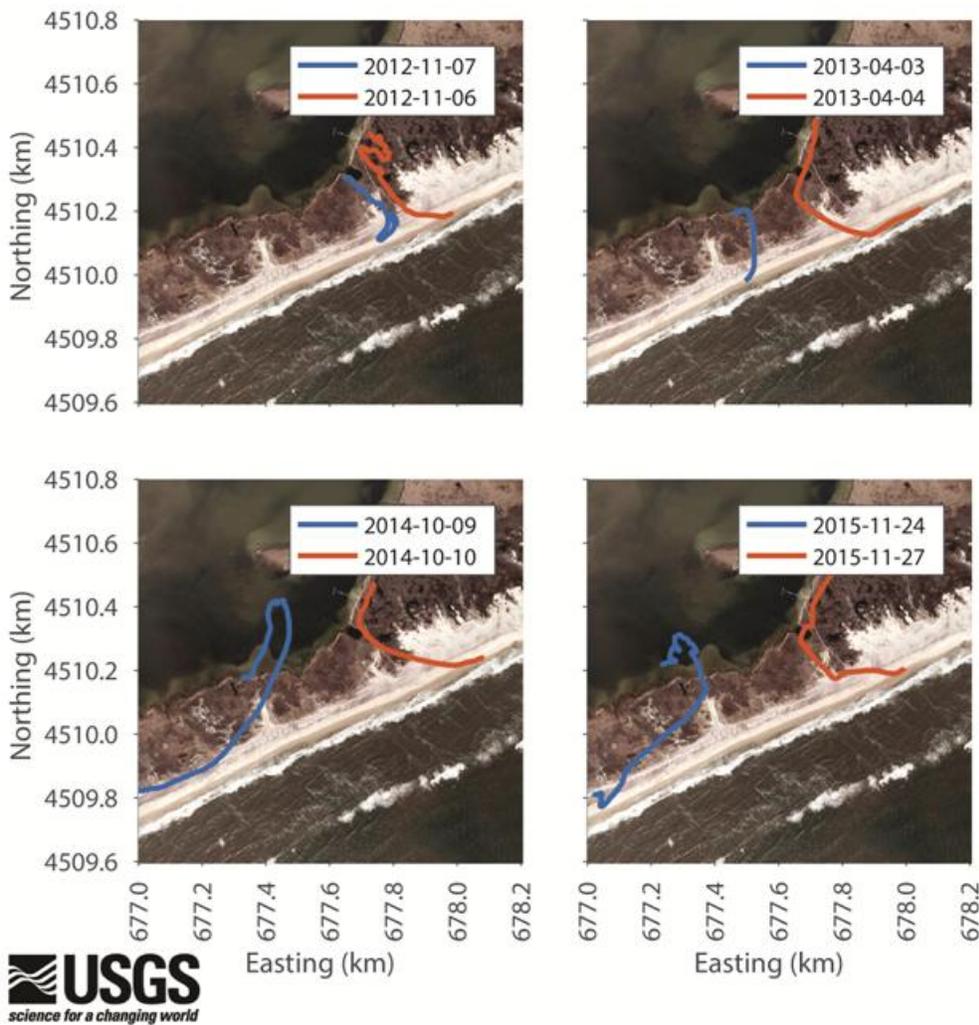

3

4 **Figure 22.** (a) Cross-sectional area of the breach from 15 bathymetric surveys (October 2014 survey in black; July 2015 survey in red); (b) time
5 series of minimum cross-sectional area (Flagg et al. 2015).

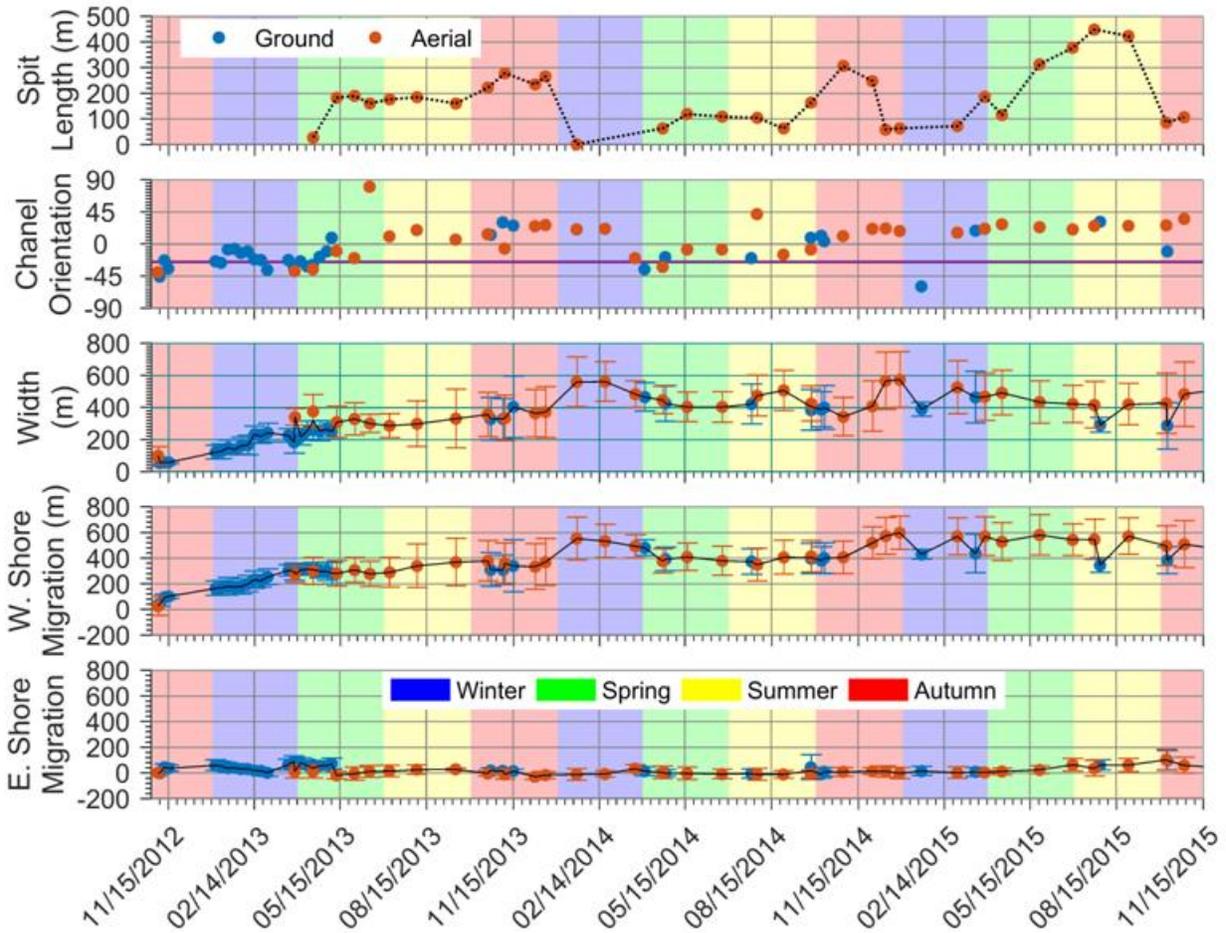

1

2 Similar changes in breach geomorphology have been documented by Nelson et al. (2016b) and
3 Nelson et al. (in review). Shoreline surveys conducted immediately following Hurricane Sandy, and
4 again in April 2013 and October 2014 show the width of the breach has increased significantly since
5 initial formation (Figure 23). Results and analysis from a series of USGS and NPS surveys between
6 November 2012 and April 2015 show the width of the breach, measured at the narrowest point
7 between the two adjacent shorelines, increased steadily during the first year (Figure 24, top panel).
8 This was followed by small narrowing of the breach which continued with few fluctuations to April
9 2015. The fourth panel in Figure 24 shows the breach has migrated west since 2012, primarily
10 through erosion of the western shoreline and little change in the eastern shoreline.

11

12 **Figure 23.** Breach shoreline change and width change between 2012 and October 2014 (Nelson et al.
13 2016).

1
 2 **Figure 24.** Changes in breach width and migration patterns between November 2102 and November
 3 2015 (Hapke pers. comm. 2016).

4 The potential for continued changes in breach geomorphology was discussed at the January
 5 workshop, particularly with regard to breach width and continued westerly migration. There was
 6 general agreement that storm activity could result in widening, but uncertainty as to the ability of
 7 Great South Bay to maintain the breach in a wider configuration, especially since the two inlets at
 8 Fire Island and Moriches are stabilized through dredging. Primary controls on inlet migration were
 9 thought to be based on barrier beach stratigraphy documented in USGS unpublished sediment cores,
 10 which show erosion resistant materials located approximately 1.5 kilometers (0.9 miles) west of the
 11 breach centerline and in the marsh resource 0.5 kilometers (0.3 miles) east of the breach (Figure 25;
 12 Hapke pers. comm. 2016).

1

2 **Figure 25.** Projected zone of breach migration based on geologic controls identified through coring by
3 USGS. Photo from GoogleEarth, May 23, 2015.

4 **Summary of Breach Impacts on Sediment Transport and Geomorphology**

5 The breach has not resulted in a significant interruption to longshore transport processes and
6 therefore is not responsible for downdrift erosion beyond the immediate vicinity of the breach.

7 The breach no longer functions as a sediment sink and bypasses material relatively efficiently via
8 ebb-tidal delta processes.

9 The cross-sectional area of the breach increased steadily for the first 2 years following formation, and
10 has remained relatively stable since this time.

11 The centerline of the breach has migrated west approximately 200 meters (656 feet) since formation
12 in 2012. Continued westerly migration is thought to be controlled by erosion resistant materials
13 located approximately 1.5 kilometers (0.9 feet) west of the current breach centerline.

1 Climate Change

2 The changing climate is altering the climatic conditions upon which traditional engineering design
3 has been based. Essentially, climate change is redefining risk for engineering projects. Historic
4 events are no longer reliable proxies for future conditions. This creates a challenging environment for
5 property owners, policy makers, investors, designers, insurers, and the general public when
6 evaluating potential projects and management options. Additionally, the impacts of climate
7 variability and extreme weather events are often felt more intensely in coastal areas because the
8 coastal zone defines the confluence of marine and terrestrial processes. For instance, coastal
9 communities are more vulnerable to increased flooding due to both sea level rise and projected
10 increases in precipitation and river flows as a result of climate change (Kirshen et al. 2008; USCCSP
11 2008; Bosma et al. 2015). Flooding probabilities are also expected to increase in the coming decades
12 due to climate change and probable increases in the intensity and frequency of coastal storms
13 (Thomas, Melillo, and Peterson 2009). This is especially true in the northeast, where ocean
14 dynamical mechanisms have the potential to further exacerbate relative sea level rise (Yin 2012).
15 This increasing vulnerability along coastlines is further heightened by the density of people residing
16 in coastal areas. It is estimated that over 50% of the population in the United States now live in
17 coastal zones, and this number is projected to increase (Wilbanks et al. 2008). Populations and
18 infrastructure are not the only elements being influenced by climate change. Natural resources and
19 coastal processes will also be affected by the projected sea level increases and extreme storm
20 conditions. As such, climate change should be a key consideration for any project located along the
21 coast.

22 The changing climate, and specifically projected sea level rise and increased storm intensity and
23 frequency, is a significant factor that is expected to impact the Fire Island area and the potential
24 breach formation and dynamics in the future. Currently, the existing technical studies evaluating the
25 post-breach conditions, as well as the potential alternatives considered for managing the existing
26 beach-open condition, have not focused on the potential impacts of climate change. Rather the focus
27 has been more geared towards the short-term impacts (1–5 years) associated with the breach opening,
28 as well as potential mid-term changes (5–15 years) expected to occur if the breach is allowed to stay
29 open. This is likely a reasonable approach when considering near term risk and comparing conditions
30 existing pre- and post-breach.

31 However, from an economic perspective and when considering more mid- to long-term conditions, it
32 is advisable to consider management alternatives and associated impacts under the lens of a changing
33 climate. For example, it is likely that due to climate change, future breaches at the location will
34 become more frequent and prevalent. Under these conditions, it may be more economically viable to
35 allow the breach to remain open, and consider additional more cost-effect adaptation and resiliency
36 options for long-term management of the Seashore.

37
38

1 **Ecological Resources**

2 The marine and estuarine resources in the vicinity of the Fire Island wilderness breach and Great
3 South Bay are affected by physical, chemical, and biological processes. Prior to the formation of the
4 breach, the ecological community in the area of the breach was primarily composed of estuarine
5 habitats and species. Existing inlets, including Fire Island and Moriches Inlets, provided the only
6 connectivity for bay water and organisms with the ocean. The formation of the breach created a new
7 connection between Great South Bay, western Moriches Bay, and the Atlantic Ocean, providing a
8 new portal through which water and organisms could transit, and allowing a greater influence of the
9 ocean on the bay's ecosystem.

10 The breach has resulted in changes to marine and estuarine resources in Great South Bay, Narrow
11 Bay, and western Moriches Bay. The affected resources include water quality, wetlands, submerged
12 aquatic vegetation (SAV), benthic communities, hard clams, finfish and decapods, and ecosystem
13 structure and processes. The information presented in this technical synthesis report for marine and
14 estuarine ecological resources addresses the current science regarding ecological changes as a result
15 of the breach in Great South Bay.

16

1 **Water Quality and Phytoplankton**

2 The term “water quality” typically describes both the physicochemical and biological characteristics
3 of a waterbody that influence the abundance and distribution of aquatic organisms, including those at
4 higher trophic levels (i.e., fish). The key physicochemical drivers of water quality include nutrients,
5 salinity, temperature, and dissolved oxygen levels. Biological parameters important to water quality
6 determinations include measures of the density, species composition, and distribution of
7 phytoplankton, harmful algae, and coliform bacteria. These biological organisms are sensitive to
8 nutrient levels, and other physicochemical parameters, and therefore provide a natural indicator of
9 water quality. Fecal coliform bacteria density and species composition are water quality measures
10 that are very useful for assessing the potential risk posed to human health from direct uses of a
11 waterbody, such as swimming or shellfish consumption. Water quality monitoring is a common
12 scientific practice used by local, state, and federal agencies throughout the United States to evaluate
13 and monitor the health of aquatic systems. Changes in water quality can be observed in the
14 physicochemical and biological characteristics of a waterbody and are easily evaluated with
15 laboratory analyses of water samples. Water quality and phytoplankton communities were included
16 in this data synthesis due to their ability to detect short- and long-term changes in water quality as a
17 response to perturbations, such as the breach documented at the Fire Island National Seashore.

18 The following section provides a synthesis and summary of available water quality and
19 phytoplankton data relevant to the Great South Bay. General trends for temperature and salinity, and
20 other physicochemical parameters, are briefly discussed in this section but are discussed in greater
21 detail in the “Physical Resources” section of this report.

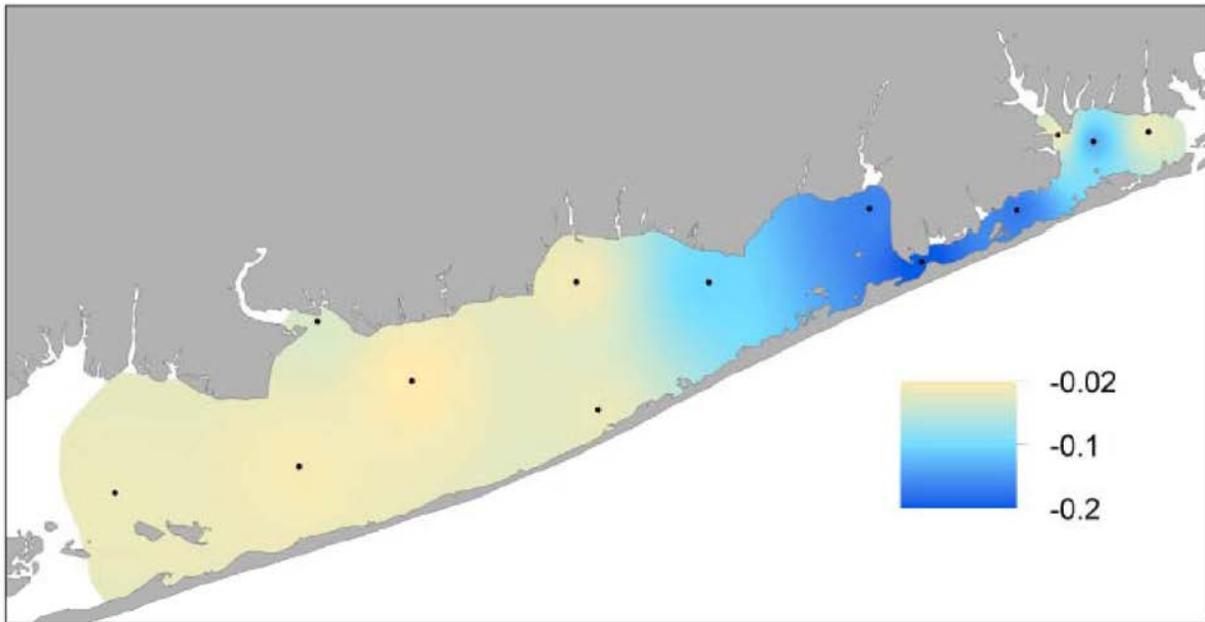

22 **Synthesis of Information: Comparison of Pre versus Post Breach**

23 ***Nitrogen***

24 Prior to the breach at Fire Island National Seashore, Great South Bay was ranked low for
25 eutrophication compared to other estuarine ecosystems. The absence of nutrient extremes in the bay,
26 according to Kinney and Valiela (2011), was attributed to the ability of the surrounding watershed to
27 retain land-derived nutrients. Prior to the breach, two inlets existed along the seashore, which
28 provided some exchange of oligotrophic ocean water with the Great South Bay. Areas of the bay
29 system located at a greater distance from the two inlets generally exhibited higher nutrient levels than
30 areas closer to the inlets as a result of the water exchange. Data collected from Bellport Bay marina,
31 which is located approximately 20 miles from Fire Island Inlet and approximately 9 miles from
32 Moriches Inlet, showed some of the highest nutrient concentrations when compared to data collected
33 closer to Fire Island Inlet (Flagg 2013). While the nutrient concentrations in Great South Bay may be
34 lower than those found in similar estuarine ecosystems, recent research suggests that farms within the
35 watershed of the bay contribute high nitrogen loads that influence nutrient concentrations,
36 particularly in areas of Great South Bay that are far removed from oceanic water exchange.

37 More recent data collections (analysis based on Suffolk County data reported in Gobler, Collier, and
38 Lonsdale 2014), performed after the breach formation, found decreased total nitrogen concentrations
39 in the areas of Bellport Bay, Narrow Bay, and western Moriches Bay (figure 26). Formation of the

1 breach shortened residence time in Bellport Bay, Narrow Bay, and western Moriches Bay, and thus
2 can reduce nutrient concentrations (Flagg 2013). The decreased nutrient levels are likely a response
3 to dilution of the nutrient rich estuarine water, a result of the post-breach increase in volume of ocean
4 water moving into the bay.

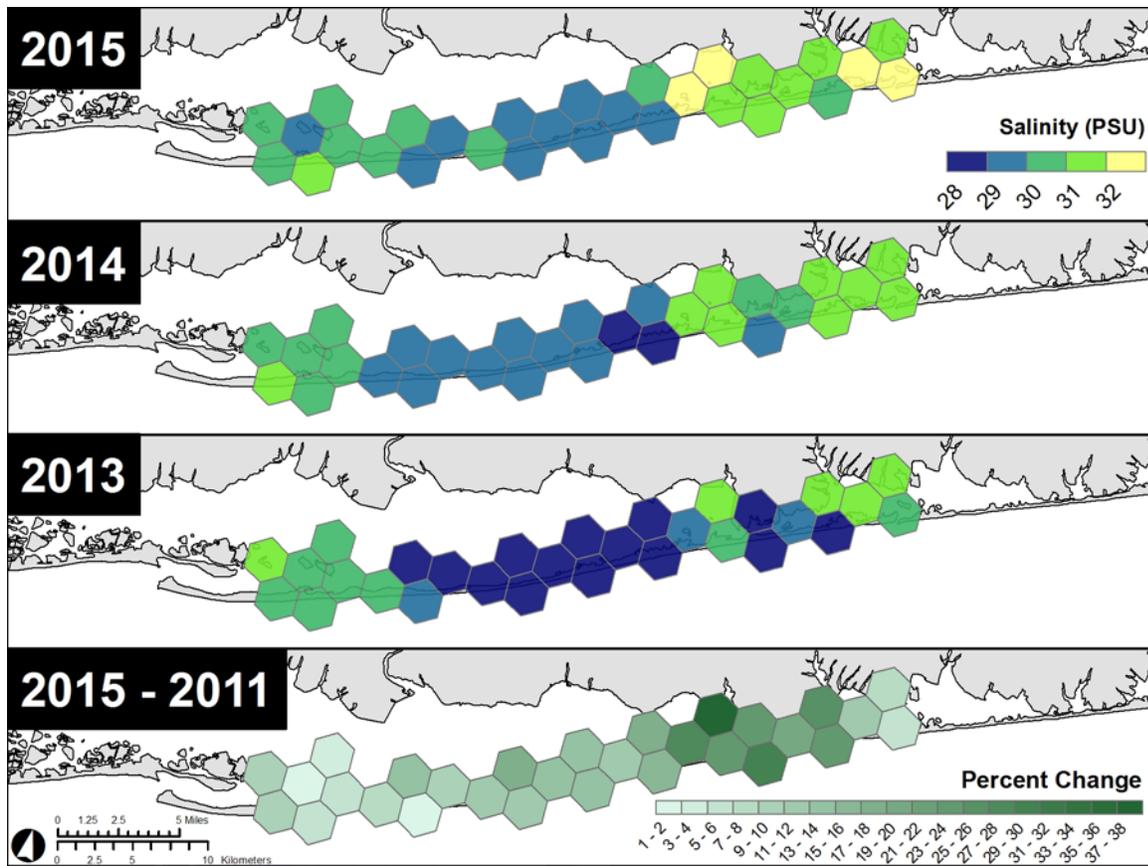

5
6 **Figure 26.** Change in total nitrogen (mg/L) from 2000 and 2008 versus 2013 (Gobler et al. 2014).

7 **Salinity**

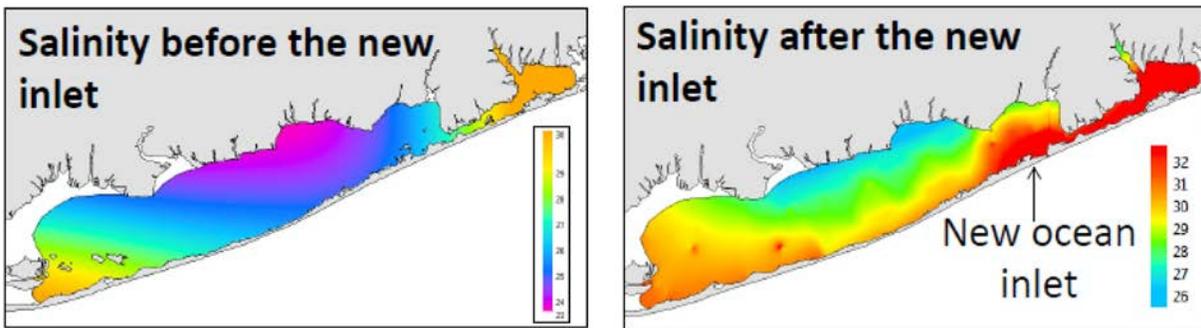

8 Data collected for this report indicate that salinity levels have increased approximately 5 psu in the
9 Bellport Bay, Narrow Bay, and western Moriches Bay areas (Figures 27 and 28) since the breach
10 formed (analysis based on data collected during a four week summer index period reported by
11 Peterson 2014 and Heck and Peterson 2016; Gobler pers. comm. 2016). The increase was attributed
12 to the influx of seawater coming through the breach. For a more detailed discussion on salinity, see
13 the “Physical Resources” section of this report.

14 **Temperature**

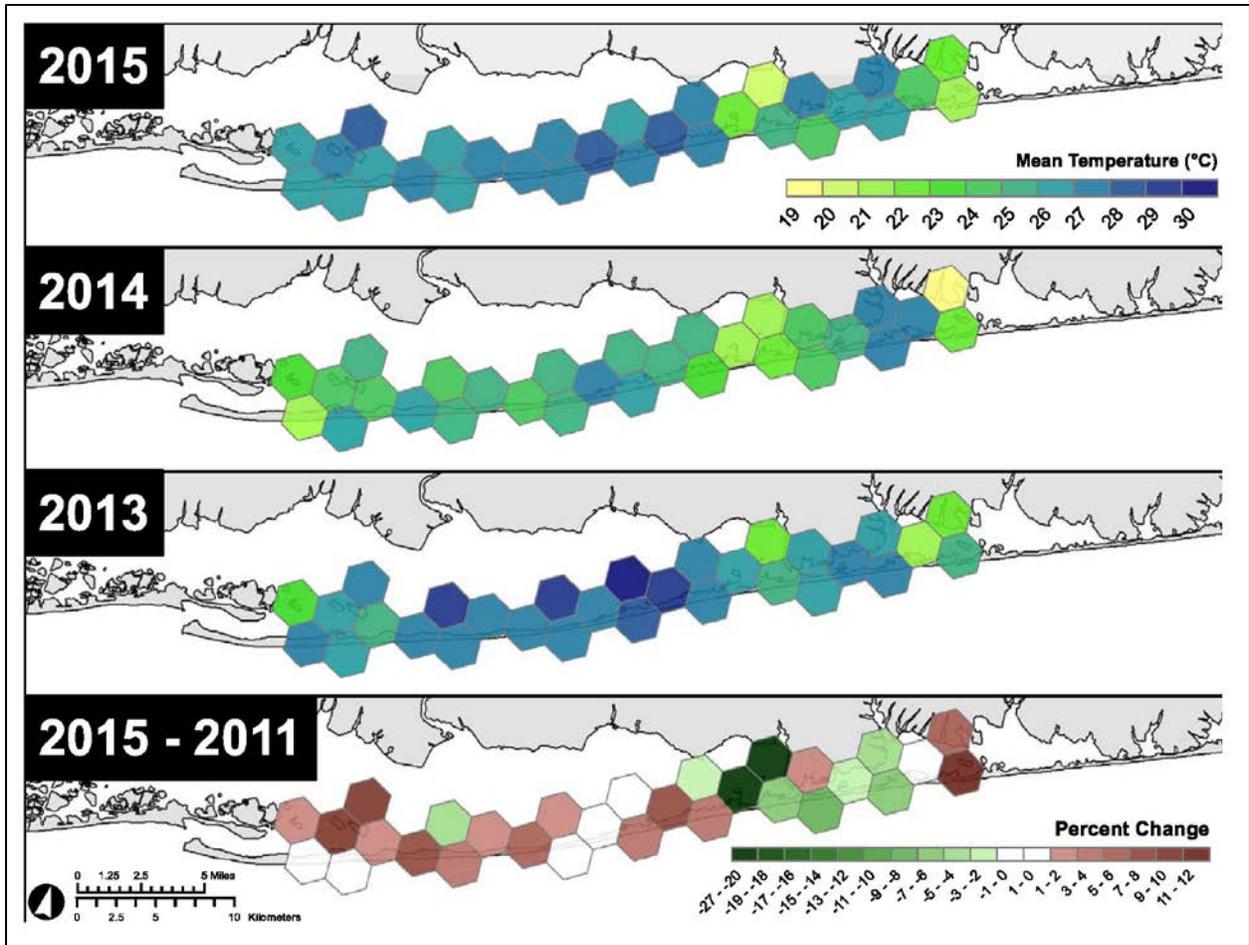

15 An analysis of data collected during a four week summer index period (as reported by Peterson 2014
16 and Heck and Peterson 2016; Gobler, Collier, and Lonsdale 2014) shows summer water temperatures
17 have decreased as much as 3°C in the Bellport Bay, Narrow Bay, and western Moriches Bay since
18 the breach formed (Figures 29 and 30). Despite findings that in the vicinity of the breach and
19 Moriches and Fire Island Inlets, there is a small decrease in summertime water temperatures (Figure
20 30), in general, water temperatures in Great South Bay are mostly dependent on air-sea interactions
21 rather than bay-ocean exchange. Changes in the heat budget of the bay due to additional water
22 exchange through the breach are planned by SoMAS for future hydrodynamic model experiments.

2 **Figure 30.** Temperature post breach (August 2013) (Gobler et al. 2014).

3 ***Dissolved Oxygen***

4 Prior to the breach, dissolved oxygen data were collected from a range of sampling stations from the
 5 Fire Island Inlet to Bellport Bay (USACE 2006b). Overall, no significant differences in dissolved
 6 oxygen existed among the sites and no distinct patterns of increase or decrease in dissolved oxygen
 7 concentrations were observed. Surface dissolved oxygen levels typically followed expected seasonal
 8 trends documented at the stations in Great South Bay, with mean dissolved oxygen levels of 9.5 mg
 9 per L (mg/L) during the May to November sampling period. Post-breach formation, trends in
 10 dissolved oxygen concentration at the immediate area of the breach have been variable. Gobler,
 11 Collier, and Lonsdale (2014) noted a net increase of approximately 1 to 1.2 mg/L in dissolved
 12 oxygen after the breach formed. Gobler (pers. comm. 2015) suggested that this increase in dissolved
 13 oxygen could potentially alleviate overnight periods of hypoxia (Figure 31). In contrast, Peterson
 14 (2014) found an overall net decrease of between 1% and 5% dissolved oxygen in Great South Bay
 15 (corresponding to concentrations of approximately 7 to 10 mg/L pre-breach and 6 to 8 mg/L post-
 16 breach) from 2011 to 2015 (Figure 32). However, areas directly adjacent to the breach showed a
 17 small net increase (1% to 3%) in dissolved oxygen concentrations during the same time period,
 18 suggesting that dissolved oxygen concentrations were variable in the years following the breach at
 19 both the immediate breach area and areas surrounding the breach (Peterson 2014). Despite these
 20 improvements in daytime dissolved oxygen, nighttime dissolved oxygen levels are still capable of
 21 reaching anoxic levels in North Bellport Bay (based on monitoring at the Bellport Bay Yacht Club)
 22 since the breach formed (Gobler 2016; USGS 2016b).

1
2 **Figure 31.** Change in dissolved oxygen (mg/L) from 2000 and 2008 versus 2013 (Gobler et al. 2014).

3
4 **Figure 32.** Dissolved oxygen (2013, 2014, 2015) and change in dissolved oxygen (2015–2011) (Heck
5 and Peterson 2016).

1 **Phytoplankton**

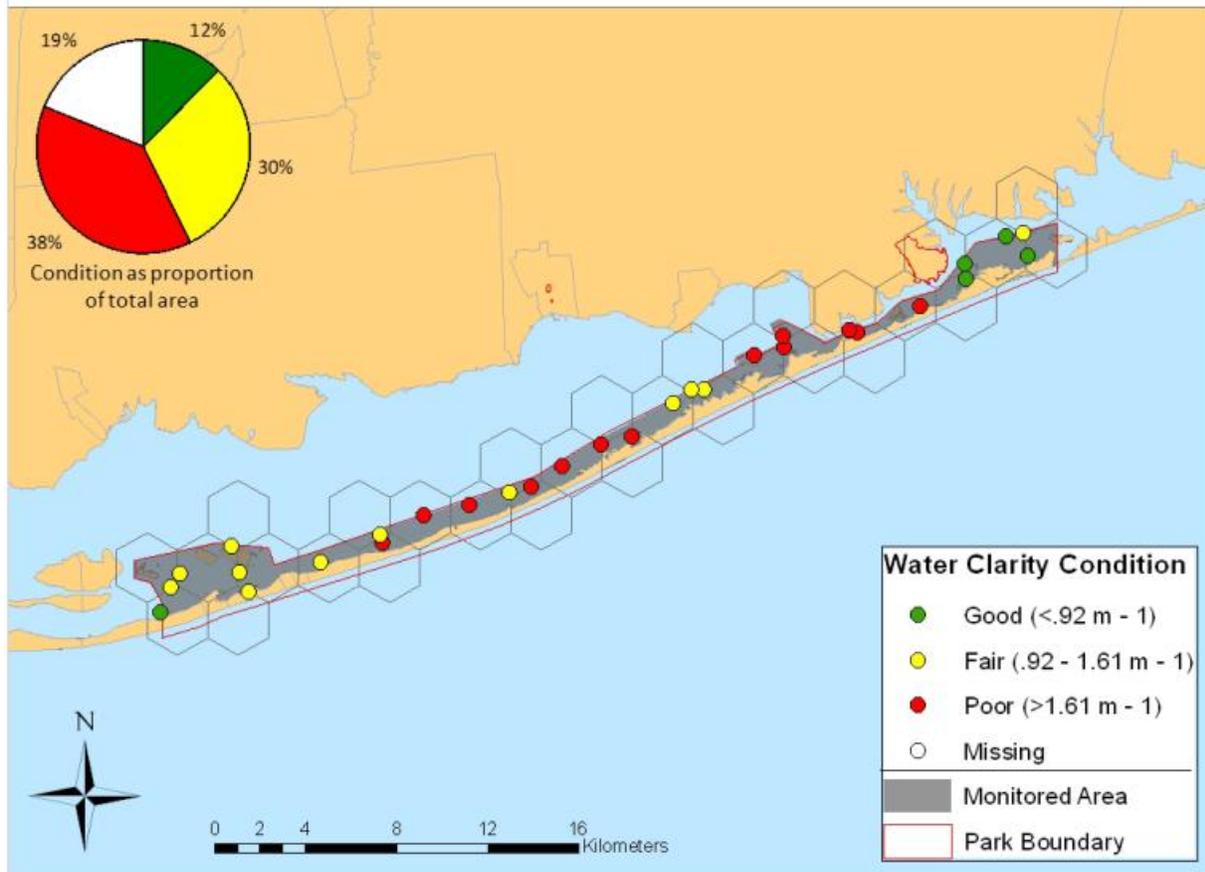

2 Water column photosynthesis (primary production) drives many biogeochemical and ecological
3 processes in coastal waters. At the base of aquatic food chains, phytoplankton drive gross primary
4 production, the rate of conversion of carbon dioxide to organic carbon and measured as grams carbon
5 per square meter per year ($\text{g C/m}^2/\text{yr}$). Phytoplankton production, species composition and timing,
6 and distribution within aquatic systems are important determinants of the quality and quantity of food
7 available for consumer organisms, and under certain conditions can have a profound negative effect
8 on physicochemical processes and water quality. Major phytoplankton blooms restrict sunlight
9 availability and reduce the photic zone depth (area from surface of water to maximum depth of
10 sunlight penetration) in aquatic systems. The photic zone is the location where photosynthesis and
11 gross primary production occur; reducing this zone can result in mortality of seagrass or other
12 organisms.

13 The die-off of phytoplankton can result in hypoxic (insufficient dissolved oxygen) conditions.
14 Phytoplankton die-off is driven by an excess of nutrients in the water column that subsequently
15 increases phytoplankton abundance. When phytoplankton become too dense in the water column,
16 mortality occurs. Bacteria then consume the phytoplankton, and through that process, respire and
17 deplete oxygen in the water column. Hypoxic conditions can cause widespread mortality in fish and
18 invertebrate populations, the extent of which is highly dependent upon the timing and severity of the
19 phytoplankton bloom. The community composition and densities of a phytoplankton bloom can be
20 highly variable, as their rapid life cycle allows them to respond quickly to changes in light,
21 temperature, and water quality. Several historical studies of Great South Bay chlorophyll and
22 phytoplankton productivity have been conducted (e.g., Lively, Kaufman, and Carpenter 1983;
23 USACE 2004c; Hinga 2005; McElroy et al. 2009), and those with most relevant data with regard to
24 understanding the influence of the new breach are discussed here.

25 Areas of an estuary near an inlet tend to have lower phytoplankton production because of active
26 mixing of estuarine waters with ocean water (Lively, Kaufman, and Carpenter 1983). A study of
27 primary production by the USACE (2004c) found that mean chlorophyll levels substantially
28 increased with distance from Fire Island Inlet and Moriches Inlet, where concentrations were
29 typically $<5 \mu\text{g/L}$. In contrast, locations furthest from inlets averaged $>10 \mu\text{g/L}$ chlorophyll-*a*. The
30 same study found that Moriches Inlet exhibited lower phytoplankton production than all other sites in
31 2001 and 2003. Similar findings were reported by Caldwell et al. (2015) who observed that water
32 clarity was greatest near existing inlets (Figure 33), and by USACE (2004c) who found that total
33 chlorophyll concentration at Moriches Inlet was significantly lower than all other sites in 2001 and
34 2003.

35 Proximity to inlets is also associated with larger form algae which provide higher quality food
36 resources for suspension feeders (Weiss et al. 2007). A study by USACE (2004c) found that stations
37 in Great South Bay located furthest from the inlets had the greatest mean abundance of smaller
38 phytoplankton, while mid-bay sites had a greater mean abundance of larger phytoplankton relative to

Water Clarity (Light Attenuation as K_d) - Fire Island National Seashore 2009

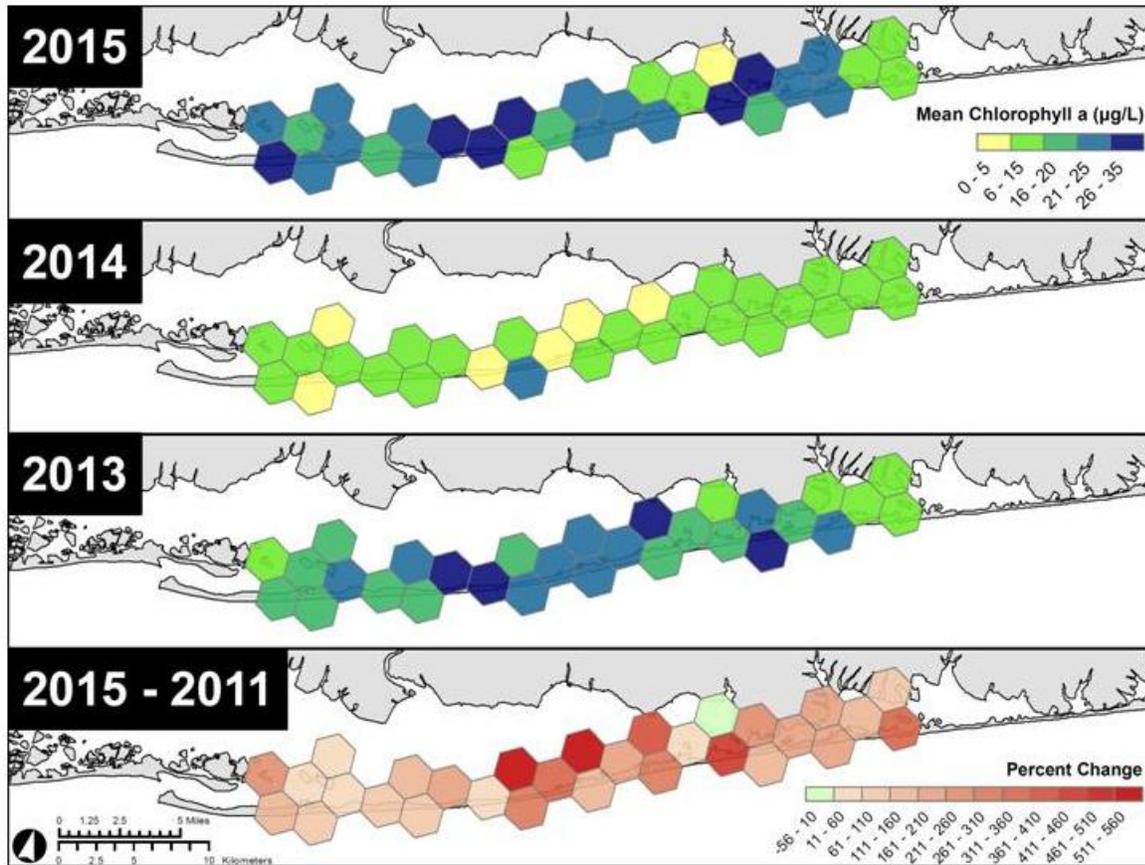

1
2 **Figure 33.** Water clarity conditions pre-breach at Fire Island National Seashore (Caldwell et al. 2015).

3 other sites, especially stations near inlets. The same study found that a station at Moriches Inlet, had
4 more large form phytoplankton (>5 μm in diameter) than other stations regardless of flooding or
5 ebbing tide. However, samples collected on the flood tide at Moriches Inlet generally contained
6 fewer small form species, had less abundant phytoplankton, and lower chlorophyll concentrations.

7 Data collected post-breach in Great South Bay show a net decrease in phytoplankton production in
8 the Bellport Bay (Peterson 2014, Gobler, Collier, and Lonsdale 2014). Prior to the breach,
9 chlorophyll-*a* concentrations in the vicinity of the breach averaged 18 to 42 $\mu\text{g/L}$. Post-breach water
10 quality monitoring in 2013 showed an initial drop in chlorophyll-*a* (16 to 20 $\mu\text{g/L}$) from pre-breach
11 concentrations (Peterson 2014). In 2014, water quality data indicated that chlorophyll-*a*
12 concentrations ranged between 6 and 15 $\mu\text{g/L}$, and were between 26 and 35 $\mu\text{g/L}$ in 2015.
13 Comparison of data from 2011 (pre-breach) and 2015 (post-breach) supports the overall observation
14 of a net decrease in chlorophyll-*a* (Figure 34) in the water column near the breach (Peterson 2014).
15 Figure 35 depicts the decline in chlorophyll-*a* since the breach formed (Gobler pers. comm. 2014).
16 Note that the comparison shown in Figure 35 is between the *average concentrations during March*
17 *for 25 years prior to the breach*, and the *average March 2013 concentration*. Comparison of years in
18 which brown tide occurred before (2000 and 2008) and after (2013) the breach in Suffolk County

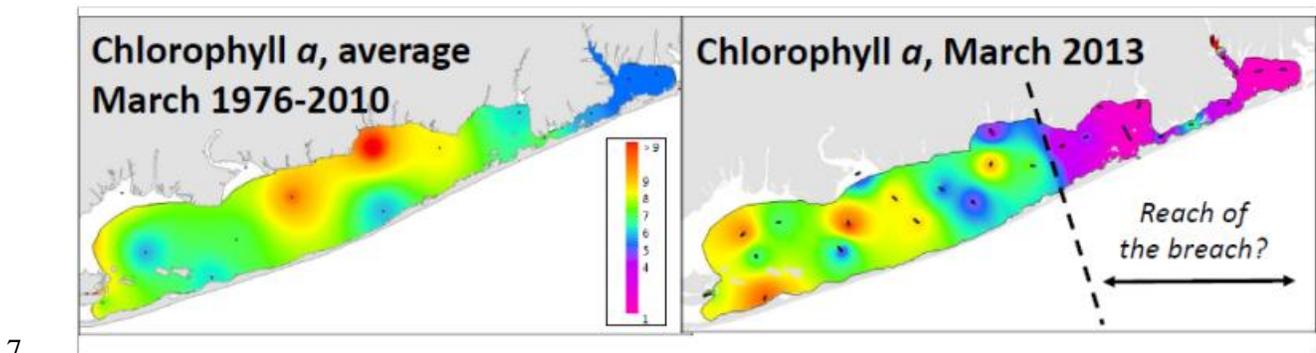

1 also indicates a substantial reduction in chlorophyll in the Bellport Bay region (Figure 36) where
2 seawater exchange has increased (Gobler, Collier, and Lonsdale (2014)).

3

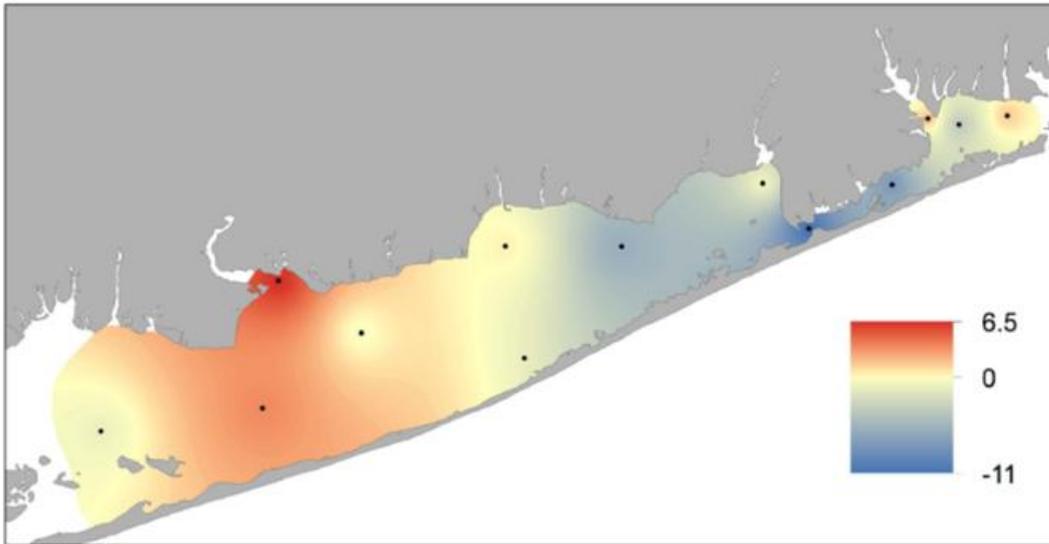

4

5 **Figure 34.** Changes in chlorophyll-a concentration in Great South Bay pre- and post-breach. Pre-breach
6 is 2011; all other years are post-breach (Heck and Peterson 2016).

7

8 **Figure 35.** Chlorophyll-a concentrations pre-breach (average value for month of March, 1976–2010) and
9 post-breach (average value during March, 2013) (Gobler, Collier, and Lonsdale 2014).

1
 2 **Figure 36.** Reduction in chlorophyll-a concentration (ug/L) in brown tide year, post-breach (2013) versus
 3 pre-breach (2000 and 2008) data (from Gobler, Collier, and Lonsdale 2014, based on Suffolk County
 4 water quality data from pre-breach brown tide years 2000 and 2008, and one post-breach year, 2013).

5 **Brown Tide**

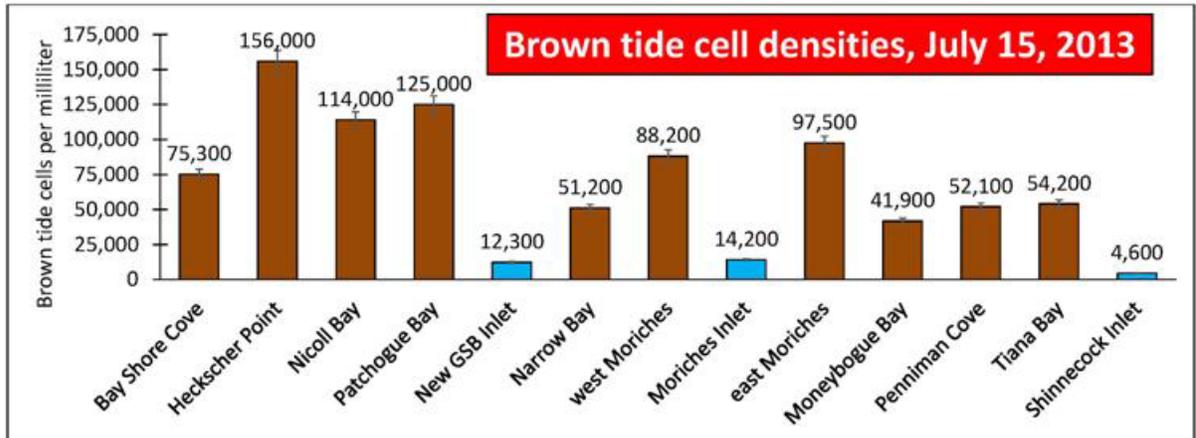

6 Blooms of harmful brown tide algae occur periodically in Great South Bay. Brown tides are
 7 considered harmful because they can cause an overabundance of water column chlorophyll,
 8 considerable reduction in light penetration, a reduction in dissolved oxygen in the water column, and
 9 are a poor source of nutrition for suspension feeders (Gobler, Collier, and Lonsdale 2014; Peterson
 10 2014; Weiss et al. 2007). Brown tide-induced water quality impacts have resulted in decreased SAV
 11 biomass and reduced hard clam landings in Long Island bay systems (Gobler, Collier, and Lonsdale
 12 2014). During very large blooms, *Aureococcus anophagefferens* becomes nearly the only
 13 phytoplankton species present. Brown tide incidence appears to be related to nutrient and dissolved
 14 organic matter in the water column (Hinga 2005). First observed in Great South Bay in the 1950s
 15 (Ryther 1954), harmful blooms were infrequent for approximately 30 years after Moriches Inlet
 16 opened and duck farming practices were changed (USACE 2009). Starting in the summer of 1985,
 17 the brown tide species *A. anophagefferens* began to experience intense periodic blooms. Although
 18 brown tide organisms have been studied extensively and the genome of *A. anophagefferens* has been
 19 mapped (Gobler et al. 2011), the ability to predict the bloom cycle in any given year is still not
 20 possible.

21 Brown tides are characterized by frequency, occurrence, and intensity. Intensity can be described as
 22 the density or concentration of brown tide cells in a bloom. Pre-breach studies of brown tide intensity
 23 showed that brown tide cell concentrations were highly variable during blooms, ranging from less
 24 than 50,000 cells/mL to more than 1 million cells/mL. In 2008, brown tide cells in the vicinity of the
 25 current breach location (Figure 37) were documented at concentrations between 300,000 and 475,000
 26 cells/mL (Gobler, Collier, and Lonsdale 2014).

1
2 **Figure 37.** Brown tide (cells/mL) in Great South Bay, June 2013 (Gobler, Collier, and Lonsdale)

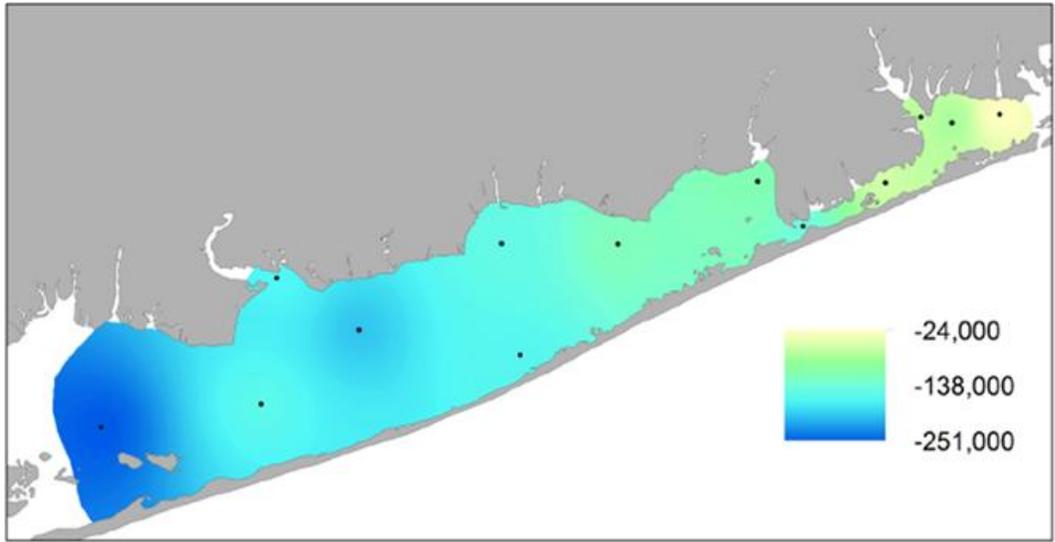

3 Since breach formation, there has been a reduction in the intensity of brown tide in eastern Great
 4 South Bay, in the areas of Bellport Bay and the Narrow Bay (Gobler, Collier, and Lonsdale 2014).
 5 Likewise, an increase in the frequency and intensity of brown tide in central Great South Bay has
 6 been documented. This is indicated in 2013 brown tide sampling which showed cell densities
 7 averaged ~400,000 cells/mL, with some sampling stations in the central Great South Bay area having
 8 densities over 1.2 million cells/mL (Gobler, Collier, and Lonsdale 2014). In the vicinity of the breach
 9 (Figure 37), cell densities were lower (ranging from about 22,800–75,900 compared with an average
 10 of 400,000) during the 2013 bloom. Figure 38 shows the 2013 brown tide cell densities in both a bar
 11 graph, and a sampling station map. The figure shows that cell densities were lower at stations close to
 12 inlets and the breach (blue bars on graph), when compared with more distant stations (brown bars on
 13 graph). Arrows on the lower figure point to sampling stations located near the inlet and breach,
 14 where cell densities are lower. Frequency of brown tide blooms has also increased in Great South
 15 Bay overall; Brown tide blooms occurred in 4 of the 13 years preceding the breach (2000-2012) but
 16 occurred in each year since the breach: 2013, 2014, and 2015 (Gobler, Collier, and Lonsdale 2014).

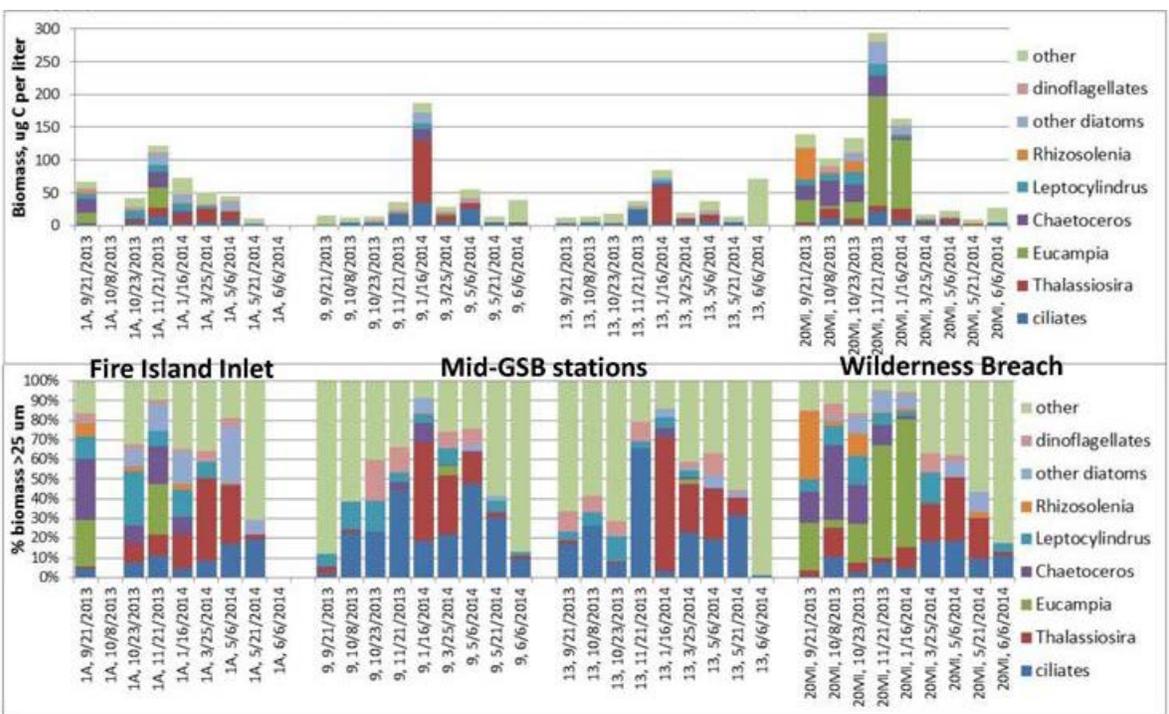

1
 2 **Figure 38.** Brown tide cells in the Great South Bay lagoon system during the brown tide bloom in July
 3 2013 (Gobler, Collier, and Lonsdale 2014).

4 More rapid reduction in the cell density of brown tide following the 2013 bloom occurred in areas
 5 closer to all inlets and the wilderness breach, with cell densities between 1 and 2 orders of magnitude
 6 lower near the inlets. Post-breach cell densities of the 2013 brown tide bloom were substantially
 7 lower than those measured during two bloom years (2000 and 2008) that occurred prior to the breach
 8 (Figure 39). Plankton community composition also differed spatially during 2013–2014, with large
 9 chain-forming diatoms dominant at the inlets, distinct from species found at central bay sites where
 10 ciliates and *Thalassioria* species were more common (Figure 40). This is notable because large form
 11 phytoplankton are a better food source for filter feeders, relative to small form species. Gobler noted
 12 a decline in the toxic dinoflagellate, *Dinophysis acumanata*, and pathogenic strains of bacteria in
 13 Great South Bay. Aerial photographs of the breach site (Figure 41) captured in 2014 showed a
 14 “flushing out” of brown tide cells resulting from water exchange between the estuarine and oceanic
 15 environments.

16 The occurrence of higher intensity brown tides in central Great South Bay compared to eastern Great
 17 South Bay may be attributable to increased water retention time in this portion of the bay brought
 18 about by new circulation patterns associated with the breach (Hinrichs 2016; Flagg pers. comm.
 19 2015; Gobler pers. comm. 2015). However, water quality conditions in Central Great South Bay,
 20 including pathogen numbers and brown tide intensity and frequency, have been getting worse since
 21 the mid-2000s (Gobler, Collier, and Lonsdale 2014).

1
 2 **Figure 39.** Average decrease in brown tide cell density (cells/ml) in Great South Bay lagoon system in
 3 brown tide years, post-breach (2013) versus pre-breach (2000 and 2008).

1

2 **Figure 41.** Wilderness breach exports brown tide (Fall 2014) (Gobler, Collier, and Lonsdale 2014).

3 ***Fecal Coliform Bacteria***

4 Fecal coliform data are used by the New York State Department of Environmental Conservation
5 (NYSDEC) to evaluate water quality in Great South Bay and to ensure that shellfish lands meet the
6 sanitary criteria for certification during the period when they are certified. Post-breach changes in
7 water quality have not affected the classification of seasonally certified¹ or uncertified shellfish lands
8 (NYSDEC 2014a, 2015). Post-breach survey data (from most recent triennial evaluation) indicates
9 that certified and seasonally certified beds of hard clams are correctly classified as such; therefore no
10 changes in classification are necessary at this time (NYSDEC 2015). There may however, be
11 potential for changing the status in the southeastern area near Narrow Bay (currently closed year
12 round uncertified) as a result of a post-breach improvement in fecal coliform levels (Barnes pers.
13 comm. 2016). There will be no decision on this status change until 2018, when the next triennial
14 evaluation is conducted.

15 **Data Gaps**

16 There were no long-term or systematic pre-breach phytoplankton data sets collected in the immediate
17 vicinity of the breach prior to 2008. The ecological consequences of the breach-related changes in
18 water clarity and quality are just beginning to be quantified, so it is uncertain whether the observed
19 changes will remain over the long term. Decreasing intensity of brown tide blooms coinciding with
20 the post-breach change in circulation patterns, are hypothesized to be associated with the formation
21 of the breach. However, both the pathogen and nitrogen loading to central Great South Bay have
22 been increasing for quite some time (prior to breach formation). Further, an increase in frequency and

¹ Seasonally certified and uncertified are designations assigned to shellfish lands by the NYSDEC. Hard clams may be taken only from areas designated as certified (or open) for the harvest of hard clams.

1 intensity of harmful algae blooms, and subsequent decrease in water quality, and failure to meet
2 sanitary regulatory thresholds for shellfish consumption was an ongoing issue pre-breach occurrence.
3 Several factors, in particular the ongoing trend in water quality reduction, natural variability in water
4 quality and phytoplankton communities, and the relatively short time period over which breach
5 effects have been evaluated, are sources of uncertainty. This uncertainty limits our understanding of
6 the dynamic long-term effects of the breach on phytoplankton, water quality, algal blooms, or
7 bacterial blooms.

8 **Summary of Changes since the Formation of the Breach**

9 The formation of the breach created a new portal through which ocean water can enter Great South
10 Bay. In Bellport Bay, Narrow Bay, and western Moriches Bay, this exchange of ocean water has
11 resulted in increased salinity, moderated water temperature, increased water clarity, decreased
12 nitrogen, decreased chlorophyll-*a*, decreased brown tide frequency, lower brown tide cell densities
13 during brown tide events, faster clearing out of brown tide cells following bloom events, and a
14 change in species composition toward larger, chain-forming diatoms.

15

1 Wetlands

2 Wetlands occurring in the vicinity of the breach are primarily tidal marshes—beds of intertidal salt-
3 tolerant grasses that are flooded and drained by the tide. These accretional environments accumulate
4 terrigenous and biogenic sediments in response to tidal flooding and plant growth. Low saltmarsh is
5 the most abundant wetland cover type on Fire Island, encompassing 670 hectares (26%) of the total
6 area (McElroy et al. 2009). Most of these marshes are located along the north shore of the barrier
7 island and consist of discontinuous patches of back barrier tidal fringe marsh. The most extensive salt
8 marshes of the Fire Island barrier are located to the west of Watch Hill and extend to Moriches Inlet
9 (Roman and Lynch pers. comm. 2016).

10 Synthesis of Wetland Vegetation Information

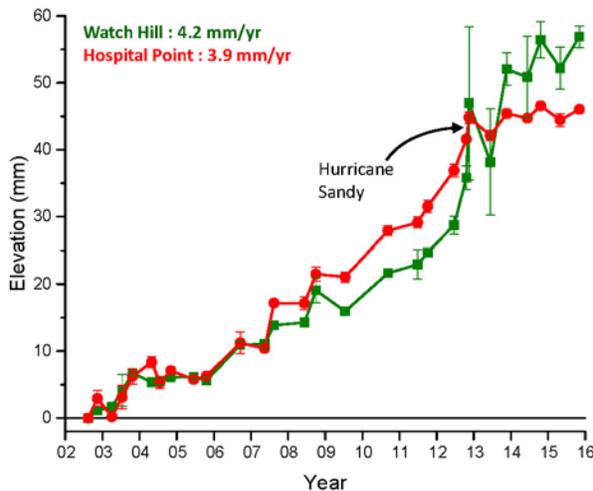

11 Fire Island supports a total of eight distinct salt marsh habitat subtypes, each with its own
12 characteristic vegetation (McElroy et al. 2009):

- 13 • **Low salt marsh** is dominated by cordgrass (*Spartina alterniflora*) and occurs at the seaward
14 border of the high marsh, along the edges of saltwater tidal creeks, and along mosquito
15 ditches that drain the high salt marsh. This is the most abundant wetland vegetation type on
16 Fire Island.
- 17 • **High salt marsh** is dominated by saltmeadow cordgrass (*Spartina patens*) or the dwarf form
18 of cordgrass; large areas dominated by spikegrass (*Distichlis spicata*), black-grass (*Juncus*
19 *gerardii*), and glassworts (*Salicornia* spp.) are also common.
- 20 • **Salt pannes** are dominated by the dwarf form of cordgrass and glassworts in shallow
21 depressions within the marsh; salinity is higher in these areas due to trapping of salt water.
- 22 • **Northern salt shrub** is dominated by groundseltree (*Baccharis halimifolia*) and/or
23 saltmarsh-elder (*Iva frutescens*) at the upland border of the high salt marsh.
- 24 • **Brackish meadow** is dominated by switch grass (*Panicum virgatum*) and saltmeadow
25 cordgrass occurring at the upland border of the high salt marsh.
- 26 • **Oligohaline tidal marsh** occurs as a narrow band between high salt marsh and salt shrub
27 vegetation, dominated by spikerush (*Eleocharis rostellata*) and twig-rush (*Cladium*
28 *mariscoides*).
- 29 • **Brackish tidal marsh** is dominated by narrow-leaved cattail (*Typha angustifolia*).
- 30 • **Reedgrass marsh** is dominated by common reedgrass (*Phragmites australis*).

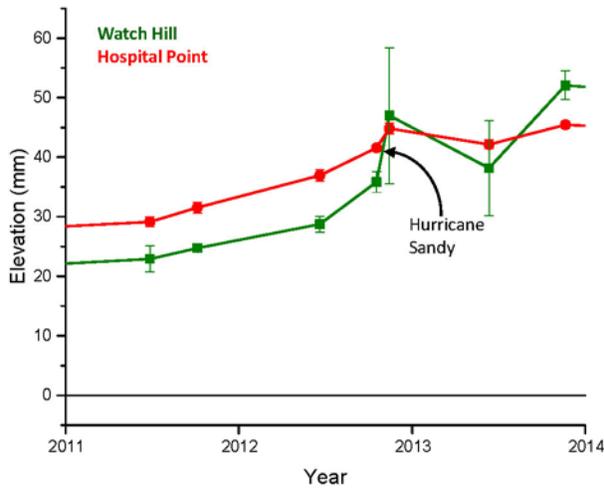

31 Marshes are dynamic ecosystems. Several processes including sediment transport from the ocean to
32 the bay, overwash events, and the formation of flood tide deltas contribute to the development of new
33 platforms for the colonization and establishment of salt marsh communities (Leatherman 1979;
34 Roman and Nordstrom 1988; Donnelly et al. 2004). Overwash delivers sediment to the marsh surface

1 nitrogen also stimulates microbial decomposition of organic matter within the underlying soils,
2 which in turn can lead to increased production of hydrogen sulfide, reduction in pH, and further
3 destabilization of marsh soils and vegetation (Deegan et al. 2007; Deegan et al. 2012; Wigand et al.
4 2014).

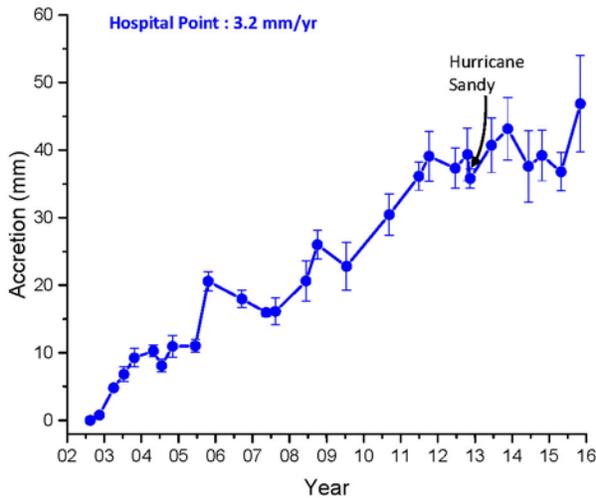

5 For long-term sustainability, increases in salt marsh elevation must keep pace with sea level rise. If
6 sea level rise exceeds marsh elevation increases, the marsh could become wetter and convert to
7 unvegetated mudflat or open water. The NPS has been using surface elevation tables (SETs) and
8 feldspar marker horizons to monitor the relationship between sea level rise and marsh elevation since
9 2002. Monitoring sites are located to the immediate east of the breach (Hospital Point Marsh,
10 Figure 42) and 8 kilometers (5.0 miles) west of the breach (Watch Hill Marsh; Roman and Lynch
11 pers. comm. 2016). The rate of increase in marsh elevation was measured as (mean \pm standard error)
12 4.2 ± 0.24 millimeters per year (mm/yr) (Watch Hill) and 3.9 ± 0.12 mm/yr (Hospital Point) (Figure
13 43). These rates are slower than those estimated for sea level rise during the recent period of 2002 to
14 2015 in the region of Fire Island which ranged from 4.74 ± 2.45 mm/yr at Sandy Hook, New Jersey,
15 to 5.93 ± 2.32 mm/yr at Battery Park, New York (Roman and Lynch pers. comm. 2016). These rates
16 are slower than those estimated for sea level rise during the recent period of 2002 to 2015 (the same
17 duration of the SET monitoring) in the region of Fire Island which ranged from 4.19 ± 2.47 mm/yr
18 (0.16 ± 0.097 inches/yr) at Montauk Point, 4.74 ± 2.45 mm/yr (0.19 ± 0.096 inches/yr) at Sandy
19 Hook, and 5.93 ± 2.32 mm/yr (0.23 ± 0.091 inches/yr) at Battery Park, New York City (Roman and
20 Lynch pers. comm. 2016). The authors of the study caveat that these rates have high variability (both
21 sea level rise and marsh elevation change) and should be evaluated with caution. However, this work
22 suggests that the short-term deficit in marsh elevation could lead to marsh submergence or
23 alternatively, marsh elevation could keep pace if the rate of sea level rise were to slow.

24
25 **Figure 43.** Marsh surface elevation change monitored using the SET method. Note the passing of
26 Hurricane Sandy, October 28, 2012. Sample size is three SETs at each site with standard error
27 presented. Rates determined by linear regression ($p < 0.0001$).

1
 2 **Figure 44.** Marsh surface elevation change monitored using the SET method, focused on a few years
 3 pre- and post-Hurricane Sandy.

4
 5 **Figure 45.** Marsh vertical accretion derived from the feldspar marker horizons. Sample size is three
 6 marker horizons at each site with standard error presented. Rates determined by linear regression
 7 ($p < 0.0001$).

8 Prior to the breach there was little salt marsh vegetation located where the breach channel was
 9 initially formed; however, as the breach migrated to the west and may continue (Figure 25), salt
 10 marsh will be lost to the breach channel (Figure 46). Small portions of salt marsh were smothered by
 11 overwash sand deposition onto the marsh surface (Figure 42). These overwash areas may be
 12 platforms for future salt marsh establishment as sea-level continues to rise.

1

2 **Figure 46.** Breach area overflight and vegetation map showing overwash areas and affected habitats,
 3 including salt marsh. Figure shows the small amount of marsh vegetation affected by overwash.

4 Post-breach changes in sediment dynamics have occurred in the vicinity of the breach, and include
 5 the formation of the flood tide delta and overwash (Roman and Lynch pers. comm. 2016). Aside
 6 from localized overwash sand deposition on the marsh in the vicinity of the breach, there did not
 7 appear to be any widespread storm-related deposition onto the marsh surface, as noted from the lack
 8 of sediment accumulation above SET feldspar marker horizons (Figure 45) and the vegetation map
 9 with overwash areas indicated (Figure 46). The aerial extent of salt marsh affected by overwash was
 10 calculated using a GIS mapping tool that allowed the overwash areas (shown in the aerial photo on
 11 the left in Figure 46) to be superimposed on the vegetation map. Affected area was calculated as the
 12 sum of the area within polygons where salt marsh vegetation and overwash intersect. This analysis
 13 indicates a very small area, approximately 25,950 m² (279,323 feet²) of salt marsh was affected by
 14 overwash.

15 There was a slight increase in marsh elevation following the storm (Figure 44), but it was probably
 16 due to peat expansion from water saturation as opposed to sediment deposition (Roman and Lynch
 17 pers. comm. 2016). Marsh migration and the health of marsh plants depend in part on water quality.

1 Improvements in water quality due to the mixing of estuarine with ocean water occurred with the
2 formation of the breach. Increased mixing reduces nitrogen concentrations in surface water,
3 potentially benefiting marsh plants. Improved water quality will provide additional benefit for the
4 development of new marsh areas on the flood tidal deltas as noted above.

5 **Data Gaps**

6 Based on a review of post-breach data, no estimations have been performed to determine the acreage
7 or type (e.g., high marsh, low marsh) of marsh habitat lost due to overwash and channel formation;
8 although vegetation maps (McElroy et al. 2009 and NPS online mapping tool) suggest little or no
9 marsh acreage exists in the immediate vicinity of the breach. Therefore, overwash-related burial
10 would be very limited. To date, no post-breach study of the expected marsh development on new
11 flood shoal and overwash area has been performed; development of new marsh is more likely to
12 occur in the future and depends on the stabilization of the newly formed flood tidal delta.
13 Understanding of the dynamic long-term effects of the breach on wetlands in the vicinity is limited.
14 However, the breach occurred recently, and marsh development takes place over longer time periods.

15 **Summary of Changes since the Formation of the Breach**

16 Changes in sediment deposition brought about by the overwash of sediment and the formation of the
17 flood tide delta have created new platforms where new low marsh could develop in the future.
18 Currently, the dynamic shifting sediment in the immediate vicinity of the breach is not conducive to
19 marsh plant colonization. However, if this area becomes more quiescent, the low marsh plant,
20 *Spartina alterniflora*, would be expected to become established. Post-breach improvements in water
21 quality that have been observed will continue to encourage marsh development. Some sites
22 immediately to the east of the breach experienced a post-breach increase in elevation, which may
23 have been a result of peat expansion due to water saturation.

24

1 Submerged Aquatic Vegetation

2 Submerged aquatic vegetation (SAV) or seagrass beds function as vital habitat for numerous
3 commercially, recreationally, and ecologically important fish and shellfish. Seagrasses play a major
4 role in the nutrient and carbon cycles, provide an important food source, nursery habitat, and
5 foraging area for various species, stabilize sediments, and improve water quality both by sequestering
6 nutrients and trapping suspended sediments and organic matter. The presence of SAV is often used
7 as an indicator of estuarine health and water quality.

8 **Synthesis of Information: Comparison of Pre versus Post Breach**

9 The two SAV species in south shore estuaries of New York are eelgrass (*Zostera marina*) and
10 widgeongrass (*Ruppia maritima*). Eelgrass, the more common of the two species, is a perennial
11 species in New York (with a few exceptions; NYS Seagrass Task Force 2009), and commonly found
12 in salinity ranges from 10 to 36 parts per thousand (ppt) (NYS Seagrass Task Force 2009).

13 Widgeongrass is a euryhaline, pioneering species that occurs sporadically in marine environments,
14 withstands abrupt salinity pulses, has a broader temperature and salinity tolerance, and grows better
15 in nutrient enriched environments that can be stressful to other seagrasses (Cho, Biber, and Nica
16 2009). Both eelgrass and widgeongrass are marine vascular flowering plants capable of sexual
17 (flowers/seeds) and asexual (clonal) reproduction. Both are commonly found in shallow water where
18 light levels are sufficient for photosynthesis, therefore the optimal depth for these species depends in
19 part on water clarity. Compared to *Zostera*, *Ruppia* has lower peak biomass and lower value as
20 habitat for SAV-associated species.

21 Areas of SAV are variable in structure (USACE 2004b). A 2003 survey found mean shoot heights
22 ranged from 7.62 centimeters to 53.34 centimeters (3 inches to 21 inches). Average percent coverage
23 was 52% in Great South Bay, 58% in Moriches Bay, and 43% in Shinnecock Bay (USACE 2004b).
24 Macroalgae, which competes with and can be detrimental to seagrasses, is often present in SAV beds
25 (USACE 2004b). Fifteen types of macroalgae were identified in association with the SAV beds in the
26 USACE study (2004b). Dominant types included wire weed (*Ahnfeltia*), the red algae *Ceramium*, and
27 the green algae *Chaetomorpha*.

28 Eelgrass provides three-dimensional structure that serves as refugia for small fish and crustaceans,
29 substrate for epiphytes and grazers, and preferred habitat for economically important species
30 including bay scallops (*Argopecten irradians*). Eelgrass is also officially designated as Essential Fish
31 Habitat for several interstate and federally managed fish species including summer flounder
32 (*Paralichthys dentatus*), which supports the most economically important recreational fishery in New
33 York. It provides forage for a number of waterfowl including brant and black ducks. Field studies of
34 eelgrass communities show that both distance from, and biomass of, eelgrass beds in estuaries has a
35 pronounced effect on the composition of the associated community of fishes, decapods, and
36 crustaceans (McElroy et al. 2009 and citations therein).

37 Seagrass is declining in Great South Bay (McElroy et al. 2009). This is well demonstrated by
38 comparisons of aerial photographs from 2002 with those from the mid-1970s that indicate a loss of
39 SAV beds fringing the mainland south shore (north side) of Great South Bay from Howell's Point in

1 Bellport west to the Robert Moses Causeway (USACE 2004b). Aerial photographs also show
2 seagrass coverage in the South Shore Estuarine Reserve was 90% lower in 2003 compared to the
3 1930s when SAV thrived in Great South Bay (NYS Seagrass Task Force 2009; USACE 2004b). In
4 the 1930s, 200,000 acres of seagrass were present (NYS Seagrass Taskforce 2009) in Great South
5 Bay. However, in 2003 SAV beds totaled just over 20,000 acres and were limited to shallow areas
6 (<2 meters [0.8 inch]) along the north shore of Fire Island and in the vicinity of the Fire Island Inlet
7 (Figure 47).

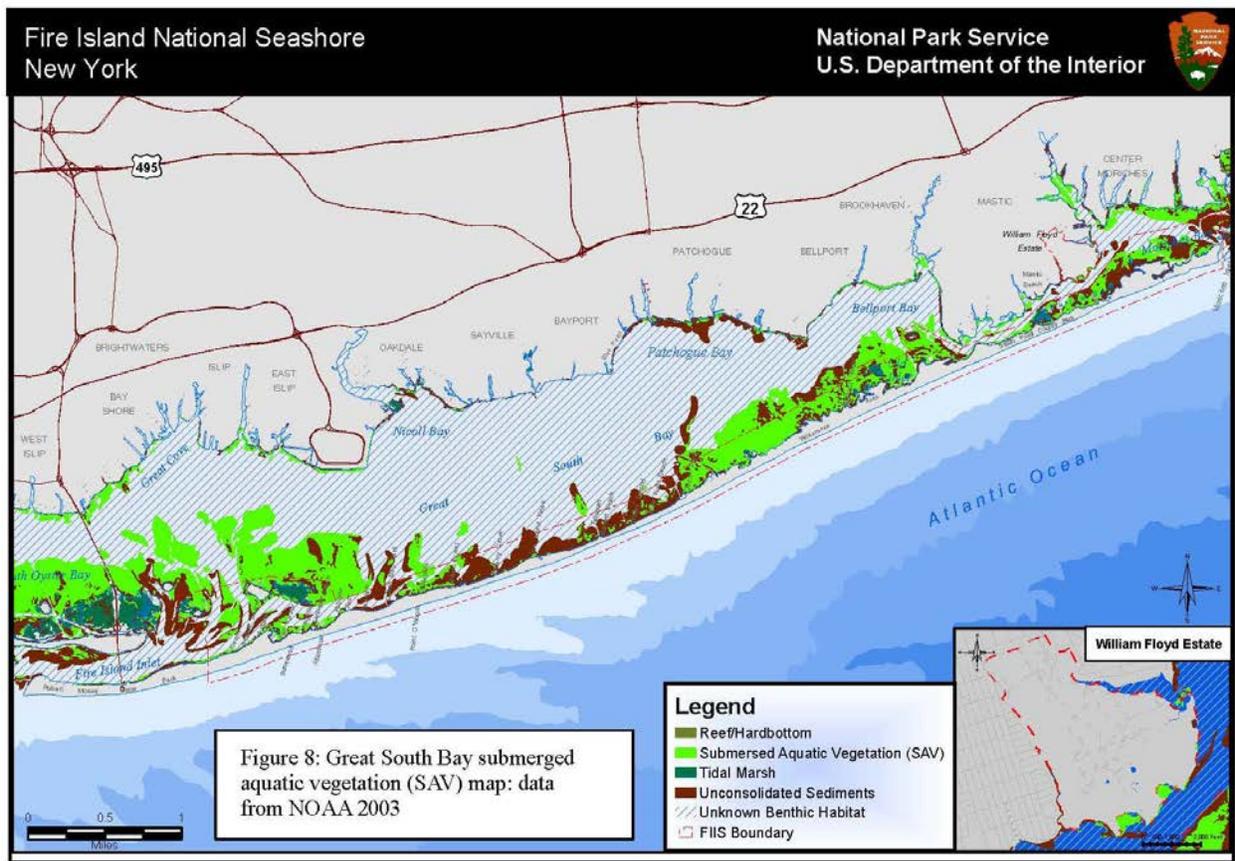

8 Field studies also demonstrate the loss of SAV throughout Great South Bay. Currently, most of the
9 eastern bay in the town of Brookhaven is devoid of any significant eelgrass beds, including the areas
10 where eelgrass was historically abundant along the Fire Island shoreline (Cashin Technical Services
11 Inc. 2011). Shallow areas between Watch Hill and Smith Point and formerly occupied by eelgrass
12 were partially covered by patches of rooted widgeon grass and attached macroalgae, and the widgeon
13 grass appeared to be taking over habitat previously occupied by eelgrass. Eelgrass beds were
14 substantially reduced or nonexistent in the shallows around east and west Fire Island. Some eelgrass
15 was observed in Babylon waters, but baymen reported a significant decrease in this area as well.

16 Declines of eelgrass have been attributed to multiple factors. In the 1930s, eelgrass nearly
17 disappeared from its range due to “wasting disease” caused by a pathogenic strain of a marine slime
18 mold, *Labyrinthula* (Short, Muehlstein, and Porter 1987). Although wasting disease was the major
19 cause of eelgrass decline, other environmental stressors including warmer water temperatures may
20 have been involved (Short and Neckles 1999). The wasting disease outbreak of the 1930s brought
21 global attention to the importance and value of seagrass, as its loss was accompanied by declines in
22 economically valuable species that use eelgrass as habitat. Although not entirely wiped out in the
23 1930s, eelgrass beds did not fully recover in the Great South Bay area until the 1950s (Hinga 2005).
24 Losses since the mid-1970s were associated with a variety of stressors, including large-scale nutrient
25 enrichment, organic enrichment, temperature increase, and sedimentation (NYS Seagrass Taskforce
26 2009).

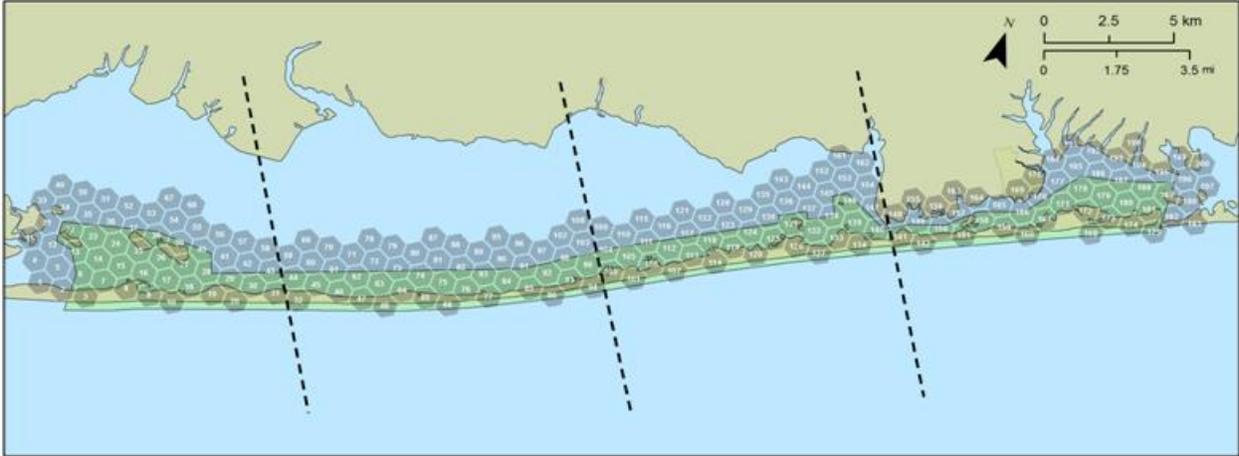

27 Post-breach changes in both water quality and substrate, two factors that influence SAV
28 communities, have been documented. The water in the vicinity of the breach is currently more
29 marine in nature due to mixing with seawater, more moderate in temperature, and contains more
30 oxygen. The more ocean-like conditions including clearer water with better light penetration, higher
31 salinity, more moderate temperatures including cooler summer temperatures, favor eelgrass. The
32 development of new flood shoals during Hurricane Sandy buried some SAV beds. However, the
33 newly created sandy shoal areas provide a platform for development of new seagrass beds in
34 locations where water depths are appropriate to support SAV. According to Peterson (2014;
35 2015a, b) initially there was significant sand overwash that smothered some SAV sites near the
36 breach and that sandbars shifted over other seagrass areas. Although the overwash areas recovered
37 the following year, the sand bar areas did not recover (Peterson 2014, 2015b).

38 Since the formation of the breach, eelgrass has increased in some areas east of the breach, despite
39 declines in other areas. This is evident from systematic field surveys conducted by researchers at
40 Stony Brook University. Initiated by NPS, this probability-based survey studied water quality and

1 SAV in 2007, 2009, 2013, and 2014 at Fire Island National Seashore (Peterson 2015a; Heck and
 2 Peterson 2016; see the vegetation monitoring grid in Figure 48). This survey found an increase in
 3 eelgrass extent and percent cover throughout the study area between 2007 and 2009, followed by a
 4 noticeable reduction between 2009 and 2013 (Peterson 2015a, b; Heck and Peterson 2016) (Figure
 5 49, left side). In the vicinity of the breach, the survey found an overall loss of seagrass between 2009
 6 and 2015, but a notable increase in eelgrass percent cover in certain areas east of the breach (Figure
 7 49, right side) where water quality has improved. At one station approximately 1 kilometer (0.6 mile)
 8 west of the breach, eelgrass moved into shallow water but had later died out (Peterson 2015a, b; and
 9 Heck and Peterson 2016). Widgeongrass was less common throughout the survey, and density
 10 changed at many locations, but the direction of change was not uniform throughout the study area.
 11 Between 2009 and 2015, widgeongrass density increased at 14 sites and decreased at 16 sites.

12
 13 **Figure 47.** Submerged aquatic vegetation distribution in south shore estuaries (based on data from
 14 NOAA 2003 and published in McElroy et al. 2009).

1

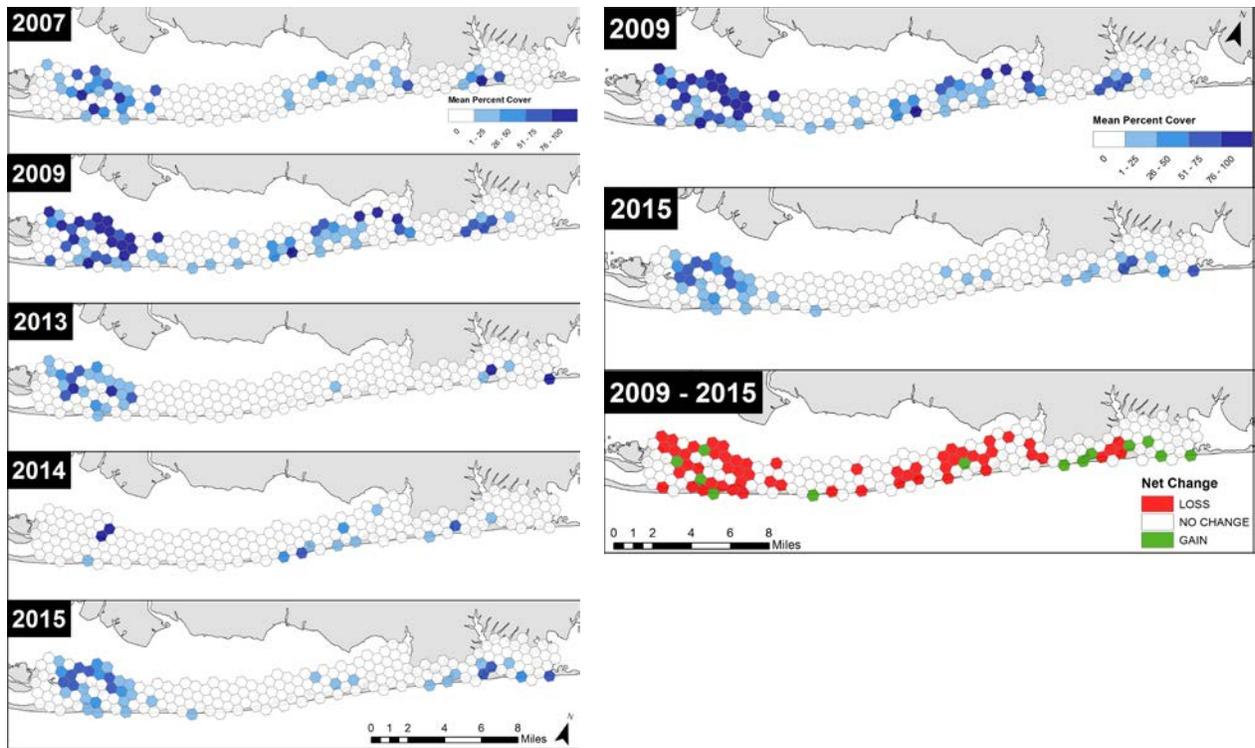

2 **Figure 48.** Submerged aquatic vegetation monitoring grid.

3 **Data Gaps**

4 There has been no long-term study of SAV distribution, species composition, and plant density in
 5 Great South Bay or in the immediate vicinity of the breach. The small amount of time that has passed
 6 since the formation of the breach limits our understanding of the dynamic long-term effects of the
 7 breach on SAV.

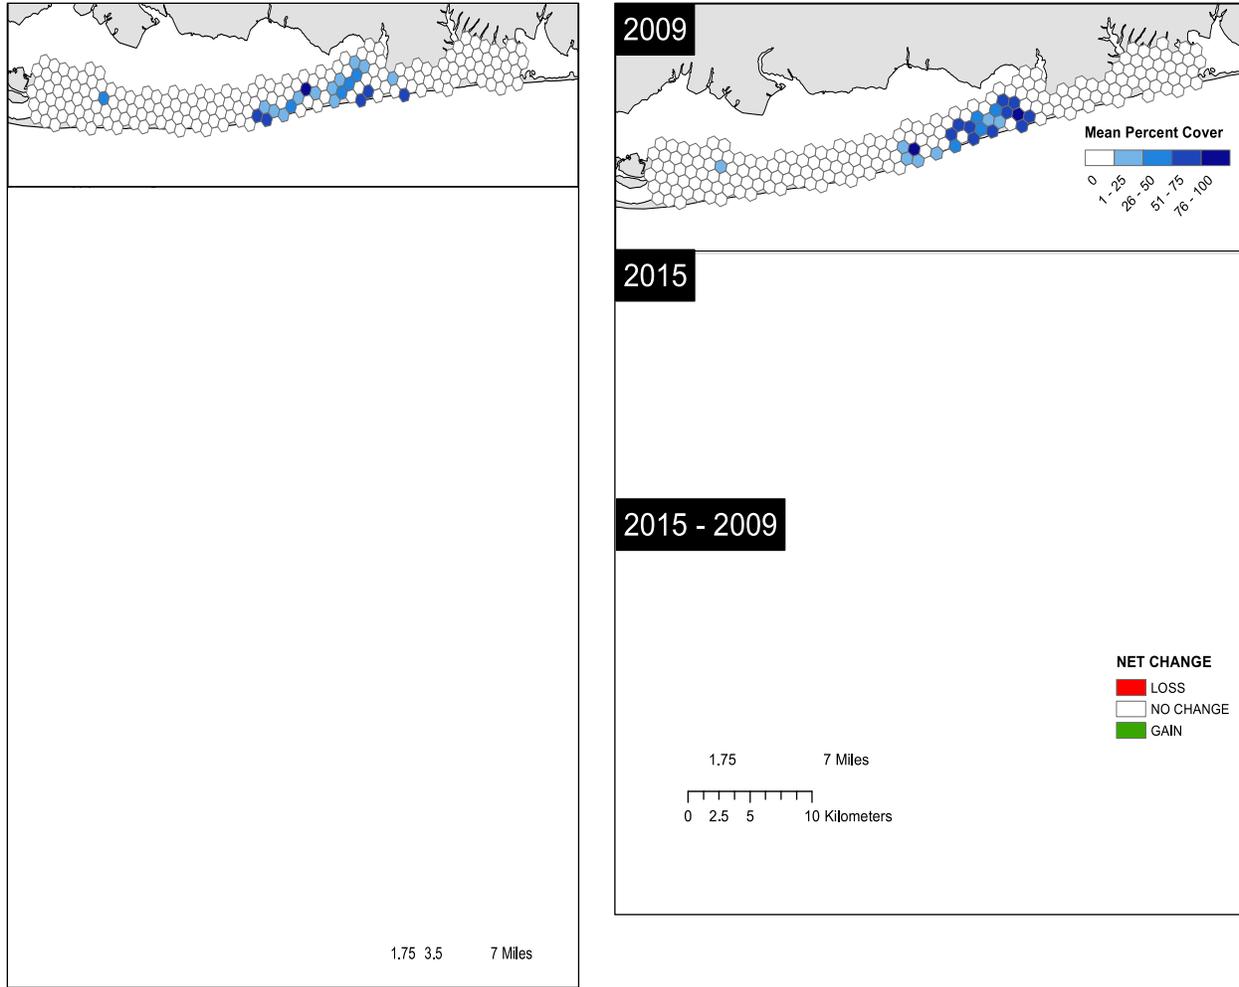

8 **Summary of Changes since the Formation of the Breach**

9 The formation of the breach has led to greater salinity, moderated summer water temperatures, and
 10 greater light penetration through the water column as a consequence of the mixing of water from
 11 Great South Bay with the ocean. This change in environmental conditions has favored the
 12 establishment of eelgrass communities just east of the breach. New platforms for SAV colonization
 13 were established following the breach in association with the flood tide delta.

3

1 Benthic Community

2 Benthic communities considered within this report include animals living in or on the sediment
3 surface in subtidal and intertidal areas of the estuary. The wilderness breach has modified the benthic
4 environment, and therefore may have had an impact on benthic communities. There are no pre- or
5 post-breach benthic community data in the immediate vicinity of the breach. Therefore no field
6 survey-based comparisons can be made to evaluate the effects of the breach. However, past studies of
7 the benthic communities in Great South Bay do inform the discussion on the nature of benthic
8 communities in this region.

9 Synthesis of Information on Benthic Communities

10 The proximity of a benthic community to an inlet has a direct effect on the composition of the
11 community (Cerrato 2001). Benthic communities near Fire Island Inlet and Moriches Inlet have been
12 described as “characteristic of a high salinity, high flow habitat” (Cerrato 2001). Abundant species in
13 these near-inlet areas included the bivalves *Mytilus edulis* (blue mussel) and *Tellina agilis* (a bivalve
14 mollusk), polychaetes (*Nephtys picta* and *Nereis arenaceodonta*), hermit crabs (*Pagurus*
15 *longicarpus*), lady crabs (*Ovalipes ocellatus*), and the sea star (*Asterias forbesi*). Similarly, a survey
16 conducted by the USACE (2004b) found that sampling stations nearest to inlets had the highest
17 overall crab abundance, with green crabs dominant (88% of total catch) and other species much less
18 common (blue crab, lady crab, rock crab, and portly spider crab each accounted for approximately
19 2% of overall catch). In contrast, areas further from the inlets had benthic communities that were
20 more estuarine and less salt-tolerant in character. Abundant species included the polychaetes
21 (*Sabellaria vulgaris* and *Trichobranchus glaucilis*), snails (*Rictaxis punctostriatus* and *Acteocina*
22 *canaliculata*), bivalves (*Mercenaria mercenaria*, *Mulinia lateralis*, and *Gemma gemma*), sand
23 shrimp *Crangon septemspinosa*, and blue crab (*Callinectes sapidus*).

24 Large-scale spatial gradients have also been described in Great South Bay (Cerrato 2001). These
25 gradients are thought to be related to differences in water column properties, which in turn are
26 coupled to the existing Fire Island Inlet. For example the bivalve, *Tellina agilis*, and the lady crab
27 (*Ovalipes ocellatus*), which prefer saltier water, were widely distributed in Islip waters but absent
28 from Brookhaven waters in eastern Great South Bay; in contrast the razor clam (*Ensis directus*)
29 which is less salt-tolerant, was abundant in Brookhaven waters but totally absent from western Great
30 South Bay (Cerrato 2001).

31 Sediment type is also a strong driver of benthic community composition. In benthic samples
32 collected in Great South Bay, macrofaunal abundance decreased with increased sediment grain-size,
33 from 41,707 individuals per square meter in mud substrates to 19,418 per square meter and 26,096
34 per square meter in sand and shell substrates, respectively (Cerrato 2001, citing Larson 2000). A total
35 of 148 distinct taxa were collected in benthic samples, with the number of taxa present increasing
36 with sediment grain-size, from 91 in mud substrates to 112 in shell substrates. The pre-breach benthic
37 subtidal community in unvegetated areas of Great South Bay, as described by Cerrato (2001), was
38 diverse, highly affected by proximity to inlets, and strongly associated with sediment type.

1 Epibenthic communities are often associated with vegetation. Vegetated subtidal areas located on the
2 bay side of Fire Island provide habitat for a number of epibenthic species including crabs. In a study
3 by USACE (2004b) epibenthic communities were evaluated along with SAV in Great South Bay,
4 Moriches Bay, and Shinnecock Bay in 2003. Common epibenthic species observed included the
5 green crab (*Carcinus maenas*), Atlantic mud crab (*Panopeus herbstii*), eastern mudsnail (*Ilyanassa*
6 *obsoleta*), grass shrimp (*Palaemonetes vulgaris*), golden star tunicate (*Botryllus schlosseri*), and red
7 beard sponge (*Microciona prolifera*). Beds of SAV exhibited a diverse epibenthic community with
8 50 different species collected during the study.

9 The occurrence of intertidal benthic communities on the bay side of Fire Island is determined by
10 frequent wetting and drying of intertidal areas. Sediment core samples completed in 2004 (USACE
11 2004a) collected a total of 13,218 organisms representing 68 different taxa using sandy sediments of
12 the bay side intertidal habitats. The dominant taxa collected in the samples included Oligochaeta,
13 Nematoda, Nematomorpha, *Corophium* sp. (a burrowing amphipod), and the amethyst gem clam
14 (*Gemma gemma*). Pitfall trap sampling in the intertidal zone revealed 1,462 individuals from 83
15 different taxa, dominated by the Ephydriidae (shore flies or brine flies) and Muscidae (house flies or
16 stable flies) families, and the ant species (*Lasius neoniger*). The amphipods *Talorchestia longicornis*,
17 *Talorchestia megalopthalma* (sand hoppers), and *Orchestia grillus* (a detritovore that feeds on
18 *Spartina* and other marsh grass detritus) were also abundant in pitfall samples. Wrackline sight
19 sampling revealed 1,268 individuals from 29 distinct taxa; dominants included the insects *Anurida*
20 *maritima* (a small wingless insect) and *Acarina* spp. (mites). Other common groups in sight samples
21 included bivalves, annelids, and amphipods.

22 Post-breach formation, the potential for changes in the benthic community prompted a workshop in
23 January 2016, where SMEs shared information and discussed the potential breach-related changes in
24 the benthic community. In general, SMEs asserted that it is likely that the benthic communities
25 closest in proximity to the breach have changed, in response to increases in salinity, water flow,
26 sediment grain size and cooler summer water temperatures, to more closely resemble benthic
27 communities that occur in the vicinity of existing South Shore inlets. The shift in the community is
28 likely to have occurred rapidly for populations of mobile, short-lived species, while populations of
29 long-lived species including hard clams are expected to show slower changes². The breach resulted
30 in the burial of intertidal and subtidal communities located where flood tide deltas have formed.
31 Formation of new habitat in response to the breach, and may have led to a shift in epibenthic species
32 composition in the vicinity of the breach. For example, according to Cerrato and Frisk, it is possible

² Benthic communities respond on a scale of months to years following a disturbance (Wilber and Clarke 2007; Van Colen et al. 2010; Kotta et al. 2009; Keay and Mickelson 2000; Dornie, Kaiser, and Warwick 2003). Less stable habitats such as coarse, clean sands in high energy zones are thought to recover more quickly than stable, muddy sediments after a disturbance, although empirical tests of this paradigm are lacking (Dornie, Kaiser, and Warwick 2003; Newell et al. 1998); recovery rates are mediated by a combination of physical (e.g., hydrodynamics), chemical (salinity, dissolved oxygen) and biological (larval transport, spawning success of brood stock) factors that differ in their relative importance in different habitats. Although decolonization of disturbed benthic habitats is generally rapid, Van Colen et al. (2010) note that divergence in benthic community development can occur late (2 years +) after a disturbance, which can cause patchiness in benthic communities.

1 that changes in salinity could lead to a shift from blue crab to lady crab communities in the affected
2 areas (pers. comm. 2016). The breach also created an opportunity for blue mussel (*Mytilus edulis*)
3 populations to develop in this area due to preference for high salinity and cooler temperatures. Blue
4 mussels were common in the area of the Old Inlet during the early 1800s when the inlet was open
5 (Cerrato, Locicero, and Goodbred 2013). After the formation of the breach in 2012, a dense
6 community of blue mussels was observed but they failed to establish a long-term population,
7 possibly due to predation or other factors (Cerrato and Frisk pers. comm. 2016). Changes in
8 epibenthic communities may have also occurred in response to the breach formation. Peterson
9 (2015a, b) found low densities of shrimp in SAV beds near the breach in 2014. The low shrimp
10 numbers were thought to be associated with high predation rates attributed to greater densities of
11 foraging fish, which likely entered the area from marine waters through the newly formed breach.

12 **Data Gaps**

13 No pre- or post-breach benthic community data exists for the area in the vicinity of the breach, where
14 water quality is most heavily influenced by the breach (Bellport Bay, Narrow Bay, western Moriches
15 Bay). The short time that has elapsed since the formation of the breach limits our understanding of
16 the dynamic long-term effects of the breach on benthic communities. Like most biological
17 communities, benthic communities can be highly dynamic, making it difficult to distinguish between
18 natural variation and changes that occur as part of a recovery or transition to a different type of
19 community. Additional monitoring of the benthic community performed over the coming years
20 would improve the post-breach monitoring dataset, resulting in a greater potential for identifying the
21 long-term, post-breach trends in the benthic community. A detailed discussion of benthic community
22 recovery is provided in Appendix A.

23 **Summary of Changes since the Formation of the Breach**

24 The breach formation resulted in conditions that favor high-flow, high-salinity adapted benthic
25 communities comparable to those Cerrato (2001) observed in the vicinity of the Fire Island Inlet.
26 Overwash and development of flood shoals (consisting predominantly of sand) have likely increased
27 the grain size in the area. The areas near the breach, including southern Bellport Bay, Narrow Bay,
28 and western Moriches Bay are experiencing increases in salinity and dissolved oxygen, and more
29 moderate water column temperatures in summer and winter. These post-breach conditions favor the
30 development of a marine benthic community, as opposed to the pre-breach conditions that favored an
31 estuarine benthic community.

32

1 Hard Clams

2 Hard clam (*Mercanaria mercenaria*) populations in Great South Bay fluctuated throughout the
3 1900s, peaked in the 1960s and 1970s, and have since declined (Frisk et al. 2015; Cashin Technical
4 Services, Inc. 2011). Poor environmental conditions and fisheries removals have been the primary
5 drivers of population declines (Starke and LoBue 2016; Frisk et al. 2015; Cashin Technical Services,
6 Inc. 2011; Bricelj 2009). Densities are currently at a historic low, with average adult density ranging
7 from 0.22–2.50 clams per square meter (average 1.1 clam per square meter) in 2008–2009 (Table 5)
8 (as reported in Cashin Technical Services, Inc. 2011, based on data from field surveys conducted by
9 the Towns of Babylon, Islip, and Brookhaven, and The Nature Conservancy (TNC)). Depressed clam
10 density has contributed to lower rates of successful spawning and reproduction (Starke and LoBue
11 2016, Cashin Technical Services, Inc. 2011). Because hard clams are broadcast spawners that require
12 proximity to spawning partners for successful reproduction, such low densities of adult spawning
13 stock greatly minimize the potential for successful reproduction and population recovery. Sharp
14 declines in fisheries harvest have mirrored the decline of hard clam populations in Great South Bay
15 since the 1970s, with hard clam landings decreasing from nearly 600,000 bushels in 1970 to less than
16 10,000 bushels in 2015 (reported in Gobler 2014; Barnes pers. comm. 2016a).

17 The loss of hard clams from Great South Bay has also meant a loss of the crucial ecosystem function
18 of water filtration and water quality improvement that hard clams once provided through suspension
19 feeding, their mechanism for obtaining food resources. Cashin Technical Services, Inc. (2011)
20 estimated that filtration rates declined 65% for Brookhaven, 84% for Islip, and 40% for Babylon
21 between 1978 and 2009. Given this, they estimated that in 2009, the existing hard clam populations
22 in Brookhaven, Islip, and Babylon took more than 3 times, 6 times, and 1.6 times longer,
23 respectively, to filter these areas than they did in 1978. The section that follows synthesizes data on
24 hard clams from before and after the breach.

25 **Table 5.** Clam density (clams per square meter) and standing stock (in millions of clams) bay-wide
26 2008/2009, by area (from Cashin Technical Services, Inc. 2011, Table 1A).

| | Total Clam Density | Seed Density | Adult Density | Standing Stock Seed | Standing Stock Adult | Standing Stock Total |
|-------------------------------|---------------------------|---------------------|----------------------|----------------------------|-----------------------------|-----------------------------|
| Babylon | 2.95 | 0.45 | 2.50 | 17.7 mil | 98.0 mil | 115.7 mil |
| Islip | 0.77 | 0.20 | 0.57 | 15.2 mil | 42.9 mil | 58.1 mil |
| The Nature Conservancy | 0.60 | 0.38 | 0.22 | 20.5 mil | 11.9 mil | 32.4 mil |
| Brookhaven | 1.83 | 0.67 | 1.16 | 49.1 mil | 84.3 mil | 133.4 mil |
| Total Bay | 1.40 | 0.42 | 0.98 | 102.4 mil | 237.1 mil | 339.6 mil |

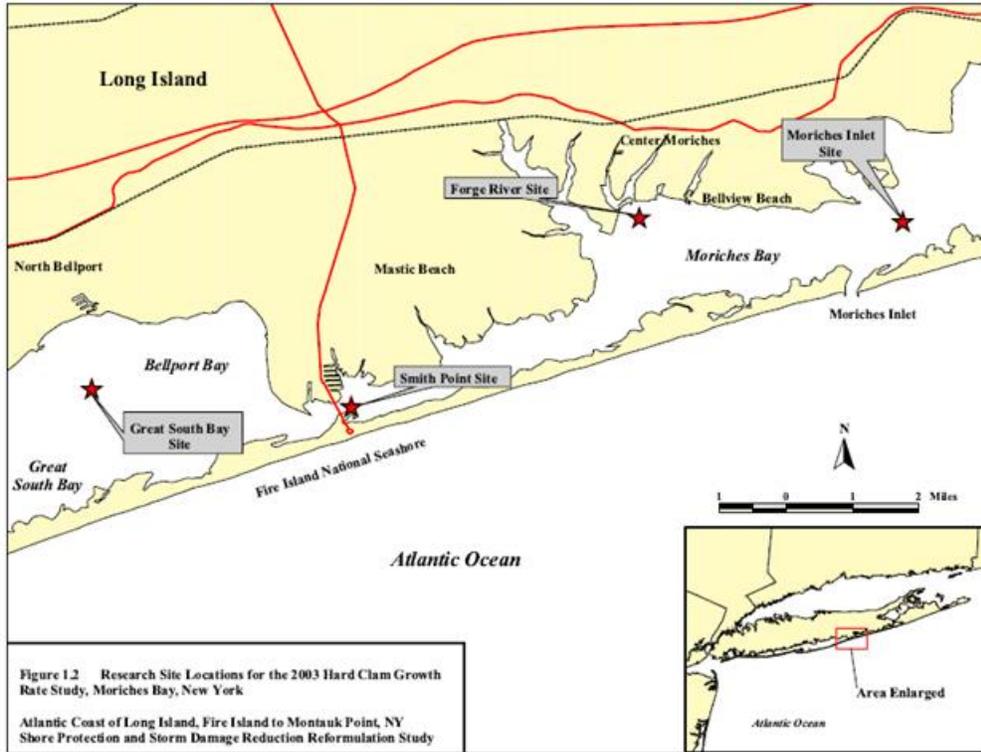

27 Synthesis of Hard Clam Information and Comparison of Pre versus Post Breach

28 The breach has increased the exchange of water and organisms with the open ocean and increased
29 flushing rates in eastern Great South Bay. Flagg and others (2015) and Hinrichs (2016) demonstrated
30 that new water circulation patterns in the bay are decreasing water residence time for eastern Great

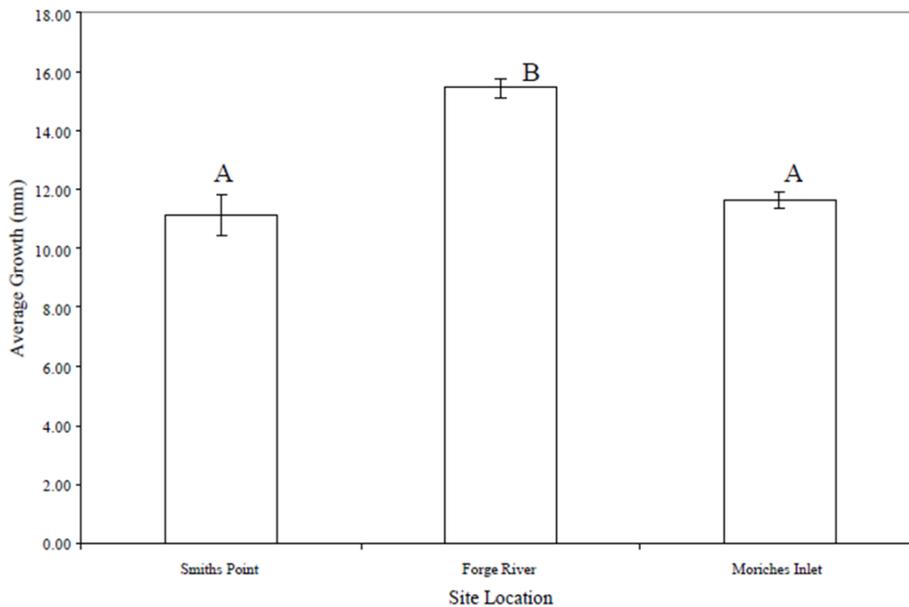

1 South Bay while increasing water residence time for central Great South Bay (refer to the “Physical
2 Resources” section). The influx of ocean water and reduced residence time of water in the eastern
3 portion of the bay has the potential to moderate winter and summer temperatures, alleviate the effects
4 of brown tide blooms by exporting small form algae to the ocean, and improve food availability for
5 hard clams by importing large form algae from the ocean (Gobler pers. comm. 2016). Evidence for
6 both positive and negative impacts of these changes in environmental conditions on measures of hard
7 clam success is summarized below. Hard clam success is determined using various metrics, including
8 increased tissue growth rates, increased shell growth rates, higher lipid content, greater condition
9 index (CI), greater specimen densities, and decreased juvenile mortality rates.

10 Several factors that affect hard clam growth and reproduction have been affected by the breach.
11 Chief among these is the availability of high quality food resources (i.e., large cell phytoplankton
12 $\geq 5 \mu\text{m}$) and potentially water temperature (optimal range for growth between 20 and 23°C; Stanley
13 1983). Sufficient food resources are essential for clam growth and reproduction. Severe food
14 limitation can be caused by brown tide algal blooms which drive down the clam CI, a commonly
15 used index of clam health and spawning potential (Starke and LoBue 2016). Brown tides are
16 dominated by the small form algae *Aureococcus anophagefferens*, which is a poor food source for
17 suspension feeding bivalves like hard clams. Algal blooms are driven by high nutrient concentrations
18 in the bay and are compounded by high residence time of water in the bay. Two blooms in the same
19 year can be devastating for hard clams, driving the CI so low that more than one spawning season
20 can be affected (Starke and LoBue 2016). Although the breach may import higher quality
21 phytoplankton into the bay, food limitation is possible right at the breach where chlorophyll-*a* levels
22 are $< 5 \mu\text{g/L}$ (Gobler pers. comm. 2015). Increased exchange of water through the breach may also
23 have decreased summer water temperatures in Bellport Bay, Narrow Bay, and western Moriches Bay
24 (Gobler 2014) which has the potential to moderate summer and winter temperatures (refer to the
25 “Physical Resources” section). In areas where the temperature reaches above or below the optimal
26 range for hard clams, the impact on hard clams would be negative. However, it should be noted that
27 data analyses conducted by SoMAS indicate that the impact of the breach on water temperature is
28 inconclusive (Flagg pers. comm. 2015; refer to the “Physical Resources” section).

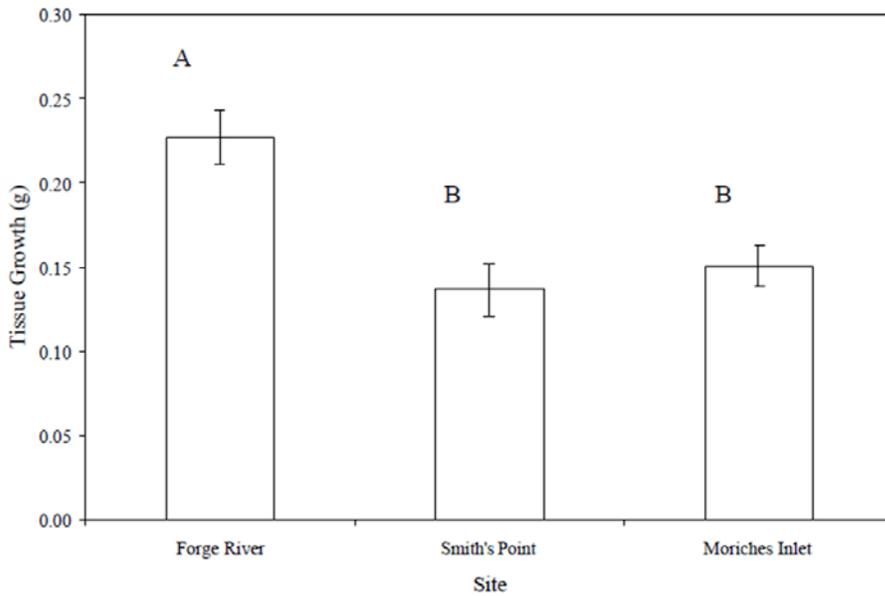

29 The important role of food limitation and temperature for hard clam growth was demonstrated in a
30 pre-breach study in Great South Bay (USACE 2004c). For this study, four cages were deployed in
31 2001 and six cages were deployed in 2003 at three stations located in Moriches Inlet, Forge River
32 and Smith Point (Figure 51). Forge River, where clam growth was the highest in both years, also had
33 the highest concentration of total chlorophyll in both years (5.9 $\mu\text{g/L}$ in 2001 and 28.59 $\mu\text{g/L}$ in
34 2003), likely a result of increased nutrient inputs from nearby sources, including historical duck
35 farms in that location (Figures 52–55). At Moriches Inlet, growth rates were significantly lower,
36 coinciding with the lowest chlorophyll measurement reported (1.5 $\mu\text{g/L}$ in 2001 and 1.06 $\mu\text{g/L}$ in
37 2003). Growth of shell peaked from June–August, whereas tissue growth rate peaked somewhat later
38 in the August–October timeframe. The relatively lower growth rates at Smith Point were attributed to
39 temperatures spiking to 27°C during the summer which above the optimal range for growth. These
40 results provided strong field-based evidence for the effect of food availability and temperature on
41 hard clam growth rates in Great South Bay.

 3 2003 (Figure 4.7 from USACE 2004c).

4 Predation can exert a strong top down control on clam populations (Virstein 1997; Kraeuter and
 5 Castagna 1980). Predation on invertebrates can increase near inlets where environmental conditions
 6 allow for marine predators as well as high salinity tolerant estuarine predators to occur (USACE
 7 2006b; EEA Inc. 2002). High juvenile predation by crabs has been observed near Fire Island Inlet
 8 (Cashin Technical Services, Inc. 2011). Predation by ctenophores and other grazers on clam larvae
 9 can also have a negative impact on the clam population in Great South Bay (Cerrato pers. comm.
 10 2016; McNamara, Lonsdale, and Cerrato 2010). Although blue crabs are a potential predator on hard
 11 clams, the impact of blue crab predation is not well understood due to limited field data on blue crabs
 12 (Bricelj 2009). Post-breach blue crab densities appear to have decreased, however lady crab
 13 populations, another potential predator on hard clams, have increased significantly (Frisk et al. 2015).
 14 Given that the breach has created a new gateway through which ocean predators can enter Great
 15 South Bay, increased predation on hard clams may be expected within areas of Great South Bay that
 16 are affected by the marine influence.

17 Salinity may also play a role in hard clam distribution patterns (Baker et al. 2005). The optimal
 18 salinity for growth is 24–28 psu (Chanley 1958) although clams can be found in salinities ranging
 19 from 10–35 ppt. Salinity appears to be less of a factor for growth rates. Increased salinity in Great
 20 South Bay caused by the influx of ocean water through the breach could have adverse effects on hard
 21 clam populations if the range of optimal salinity for survival is exceeded (Barnes pers. comm. 2016b)
 22 although there are no recorded incidences of this. Additionally, high salinity water favors the growth
 23 of QPX (Quahog Parasite Unknown), a hard clam parasite that could have negative effects on the
 24 hard clam population (Perrigault et al. 2012). Taken together, this information indicates that the
 25 change in salinity as a result of the breach has the potential to create unfavorable conditions for hard
 26 clams.

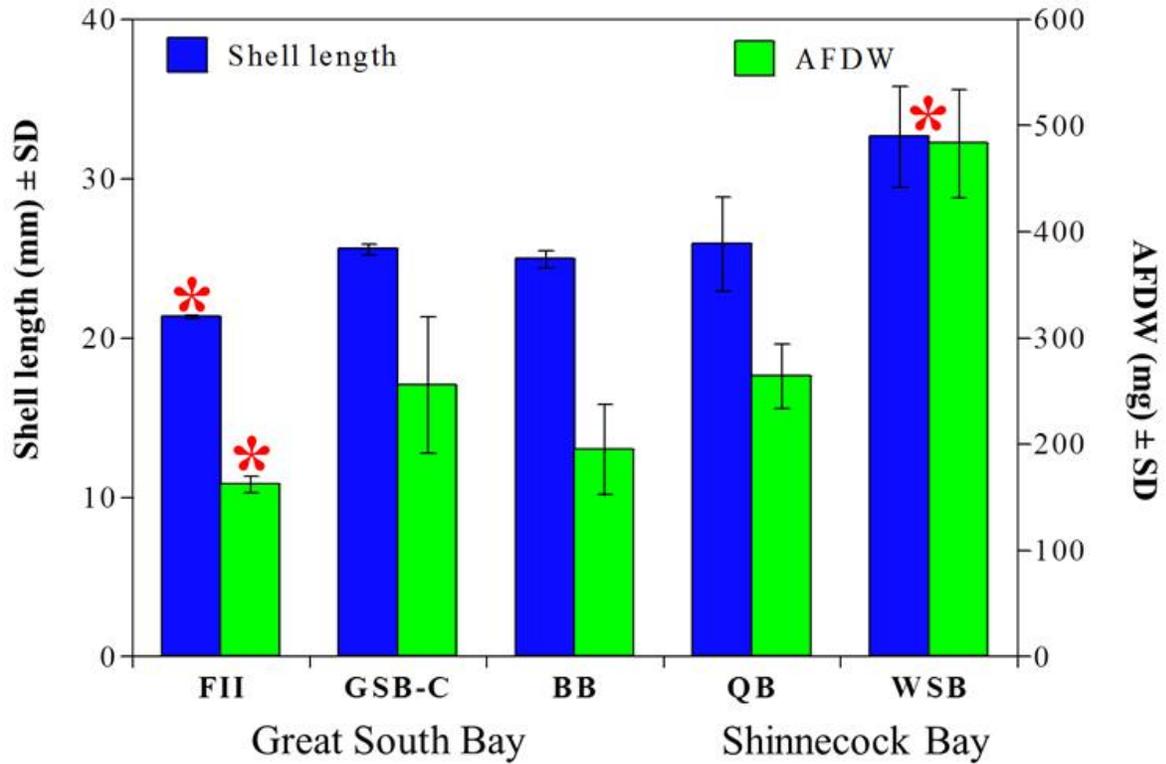

27 Prior to the breach, researchers examined the hypothesis that exchange of water with the open ocean
 28 would increase the success of hard clams in the Long Island South Shore Estuary by improving the

1 availability of high quality food resources (Gobler 2014; Weiss et al. 2007). Cage studies were
2 performed pre-breach in 2005 and 2014 under post-breach conditions by deploying and monitoring
3 cages of locally sourced clams at three stations in Shinnecock Bay and at three stations in Great
4 South Bay (Figure 56). From April to November, water quality, physical attributes, and biological
5 attributes were sampled. Central Great South Bay sites had significantly faster tissue and shell
6 growth rates, lower mortality rates, higher lipid content, greater CI, and greater densities compared to
7 sites near an inlet (Figures 57–58). Lower measures of success observed adjacent to the inlets were
8 attributed to cooler temperatures, limited phytoplankton production, and suspended organic matter as
9 food sources. In central Great South Bay locations, clams were more successful due to optimal
10 temperatures and the presence of abundant high quality food, including cells $>5\mu\text{m}$. This is consistent
11 with the findings of Newell et al. (2009) who found that reduced reproductive output appeared to be
12 associated with abundant small phytoplankton cells which clams are unable to use as food. Gobler
13 (2014) and Weiss et al. (2007) additionally found that prior to the breach, clams at the Bellport Bay
14 site had particularly low rates of tissue growth compared to other sites, which was attributed to the
15 presence of dinoflagellates and higher than optimal summer temperatures.

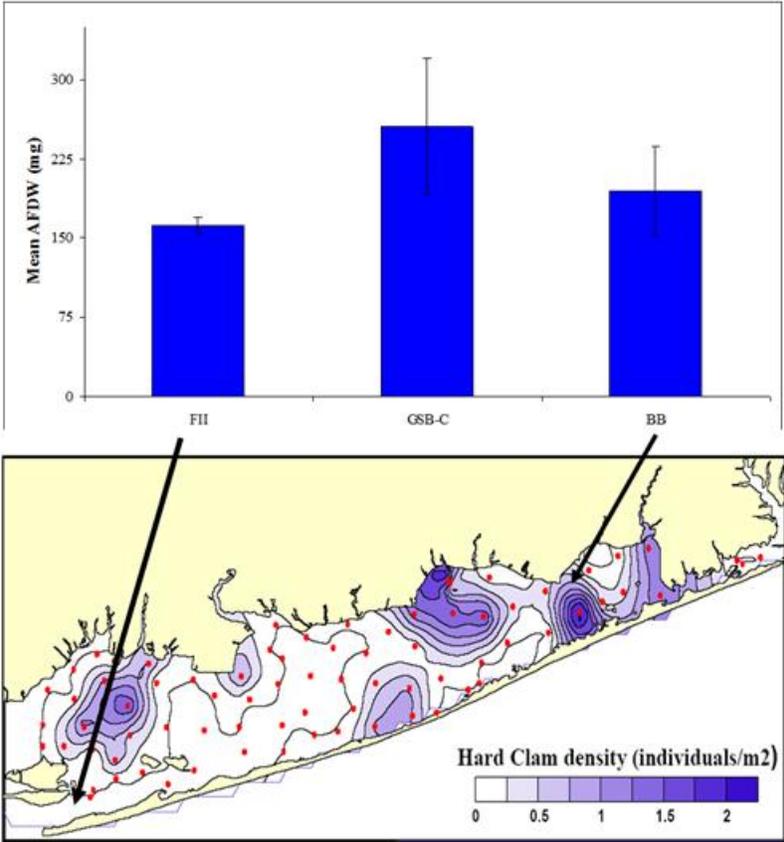

16

17 **Figure 56.** Location of study sites (from Gobler 2014). BB=Bellport Bay, C-GSB=Central Great South
18 Bay, GSB=Great South Bay, SB=Shinnecock Bay, SI=Shinnecock Inlet, WSB=Western Great South Bay.

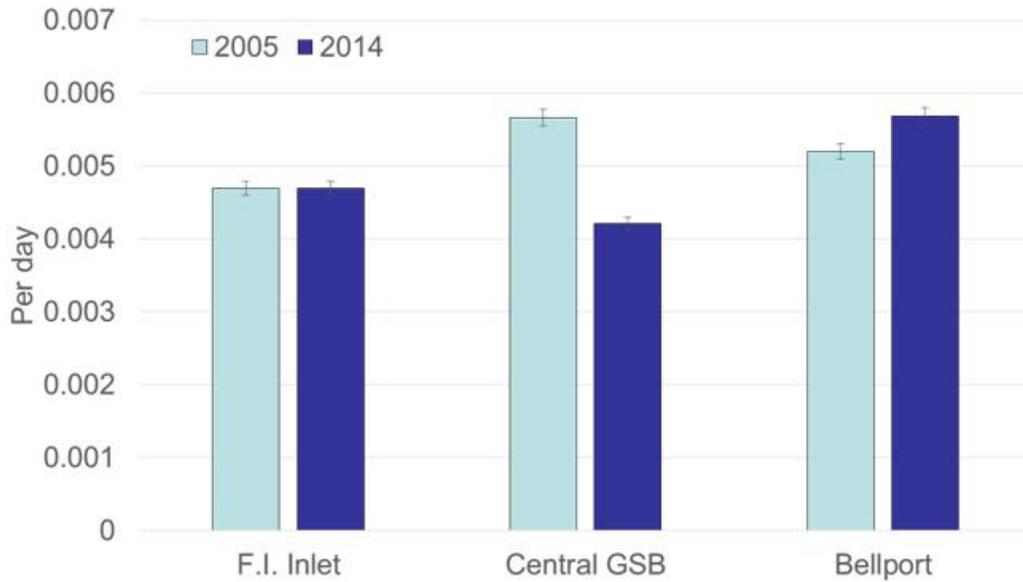

1

2 **Figure 57.** Shell length and biomass (ash-free dry weight, AFDW) at each site (from Gobler 2014). West
 3 Shinnecock Bay (SB) had significantly longer shell lengths than Quantak Bay (QB), Fire Island Inlet (FII),
 4 Central Great South Bay (GSB-C), and Bellport Bay (BB). All clams in non-inlet locations were
 5 significantly longer than clams in Fire Island Inlet.

1
 2 **Figure 58.** Mean AFDW at each site (from Gobler 2014). Red dots indicate randomly selected sampling
 3 stations. BB=Bellport Bay, FII=Fire Island Inlet, and GSB-C=Central Great South Bay.

4 Since the breach formed, measures of clam success have greatly improved for Bellport Bay. Gobler
 5 (2014) repeated his hard clam caging experiment during 2014 after the breach formed. Sites were
 6 studied from April to November and were a subset of those from the 2005 study located in Fire
 7 Island Inlet, central Great South Bay, and Bellport Bay (Figure 56). Results indicated that, in contrast
 8 to the 2005 results, growth rates were greatest for juveniles in Bellport Bay, Narrow Bay, and at Fire
 9 Island Inlet and lowest in central Great South Bay (Figure 59). However, direct comparisons between
 10 the 2005 and 2014 studies were hindered due to a high temperature anomaly and a brown tide
 11 occurrence in 2014. Nevertheless, the study highlights an emerging geographic pattern: clam growth
 12 rates have improved in Bellport Bay from 2005 to 2014 but have worsened in central Great South
 13 Bay in that same period. This suggests that conditions in Bellport Bay have improved for hard clams
 14 since the breach formed, while conditions in areas located west of the breach in central Great South
 15 Bay have continued to decline along with hard clam populations.

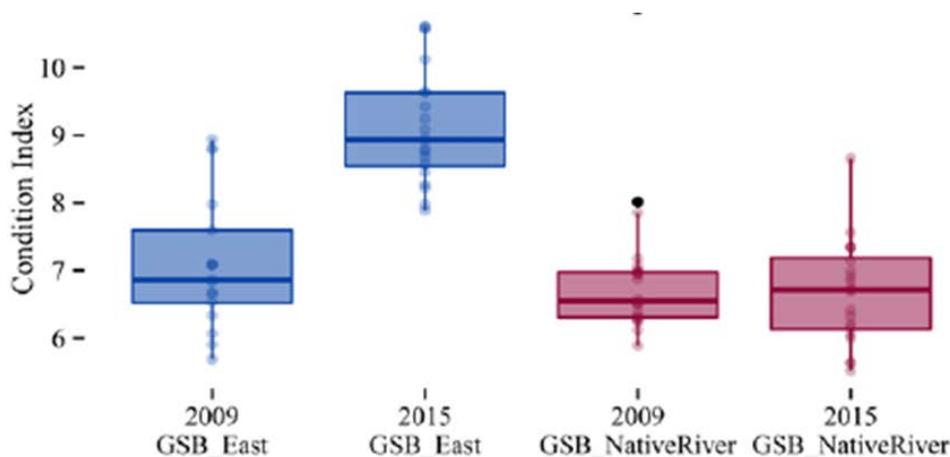

1
 2 **Figure 59.** Instantaneous growth rates of hard clams, 2005 versus 2014, most similar cohorts (from
 3 Gobler 2014).

4 Improved measures of clam success in Bellport Bay after the breach have also been noted by Starke
 5 and LoBue (2016). Clams collected before and after the breach in Bellport Bay show marked
 6 differences in growth rates (Greene 1978; Starke and LoBue 2016). Whereas prior to Hurricane
 7 Sandy, clams in this location had slow growth rates and chalky white shells due to the acidic
 8 sediment in which they lived. Clams collected in Bellport Bay after Hurricane Sandy have secreted
 9 large and healthier-appearing growth rings in their shells, indicating improved growth rate and
 10 sediment habitat condition (Figure 60). Starke and LoBue (2016) also noted improvements in CI
 11 values for clams in Bellport Bay. Researchers sampled 20 individuals of naturally occurring clams
 12 from the same locations on the same date. The results show a striking improvement in CI from before
 13 the breach in 2009 compared to after the breach in 2015 at Bellport Bay, whereas CI for central Great
 14 South Bay was relatively unchanged over the same time period (Figure 61) (Starke and LoBue 2016).
 15 These improvements in clam growth and CI are attributed to improvements in water quality, as
 16 increased rates of flushing are able to locally suppress blooms of brown tide algae and improve food
 17 quality in Bellport Bay (Starke and LoBue 2016).

1
2 **Figure 60.** Hard clams collected in Bellport Bay after Hurricane Sandy (from Starke and LoBue 2016).

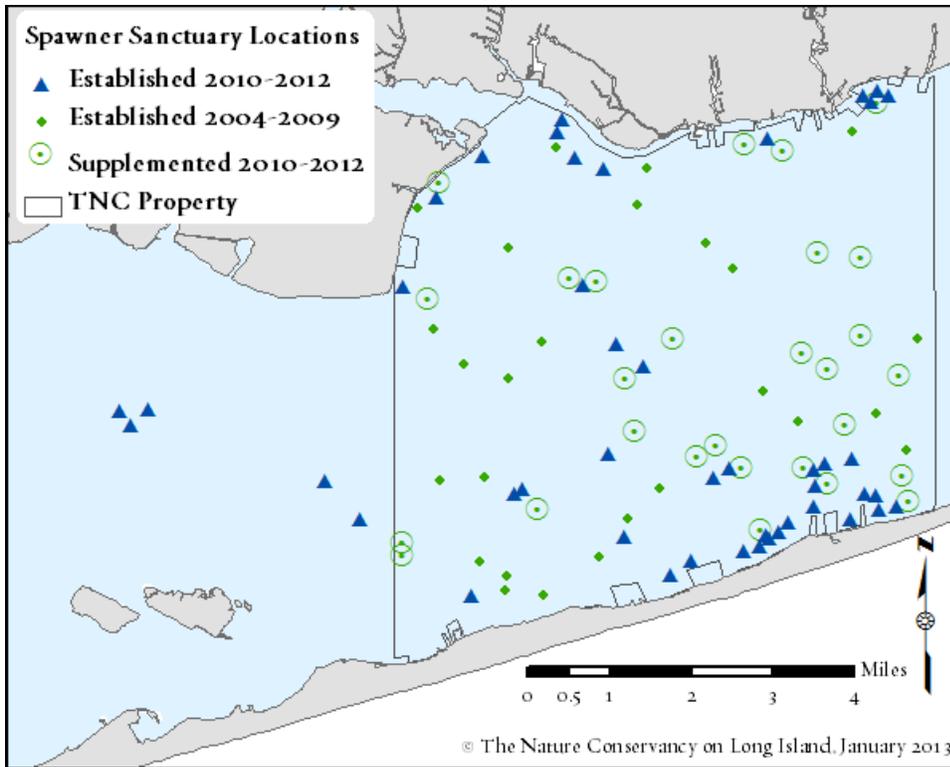

3
4 **Figure 61.** Boxplots displaying mid-November condition index measures at eastern Great South Bay /
5 Great South Bay east and central Great South Bay / Great South Bay native river sites (from Stark and
6 LoBue 2016).

7 Despite improved measures of clam success, there has been no reported change in the size of the hard
8 clam population in Great South Bay since the breach formed. Landings data from before and after the
9 breach formed indicate no major change in the number of clams harvested from Great South Bay
10 (Barnes pers. comm. 2016a). However, given that hard clams require at least 4 years to attain
11 harvestable size after settlement, any recovery in hard clam populations brought about by the breach
12 would not yet be reflected by harvest statistics. There are no fisheries-independent bay-wide surveys
13 of clam population size in Great South Bay; therefore, the response of the hard clam population
14 standing stock to the change in environmental conditions resulting from the breach remains

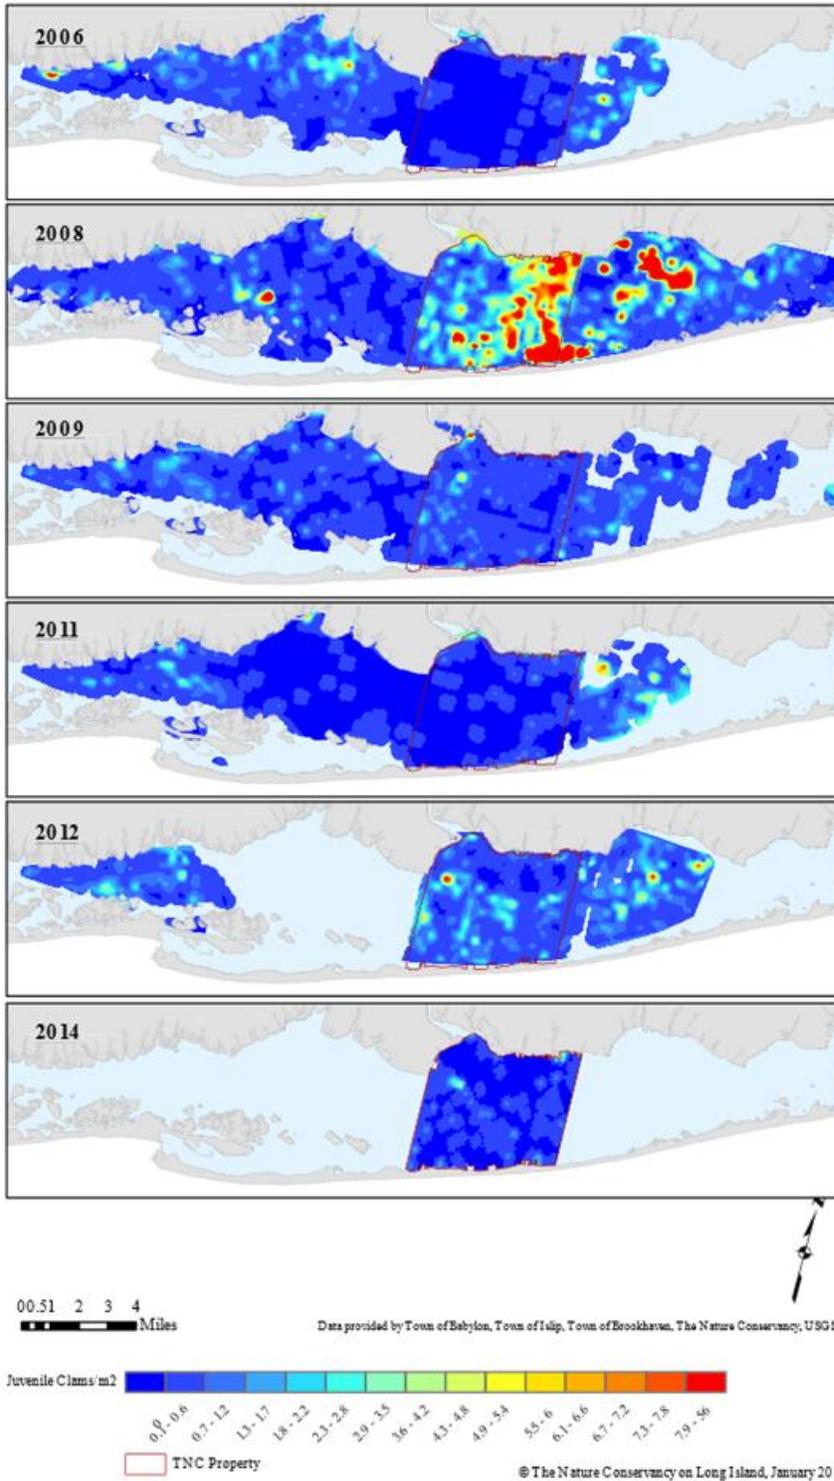

1 unknown. Although environmental conditions that favor hard clam success have occurred since the
2 breach, it is not well understood whether these improvements will be able to overcome the low
3 spawning and reproductive success that has resulted from extremely low clam densities throughout
4 the bay.

5 Considerable effort has been focused on restoring hard clams to Great South Bay. TNC has created
6 “spawner sanctuaries” since 2004 by stocking local stock from Long Island Sound and other nearby
7 estuaries (TNC 2013). Given what is known about the distribution and size classes of clams in Great
8 South Bay, and what is known about the physical forcing factors that influence the distribution of
9 juvenile hard clams such as wind, currents, and dispersal, evidence suggested that stocking large
10 numbers of adult clams in the spawner sanctuaries could increase recruitment in Great South Bay
11 (TNC 2013). In spawner sanctuaries, clams are stocked at high density (>10 per square meter) on
12 natural bottom in areas protected from harvest (GSBH CWG 2011). There are 108 restocking sites
13 covering 81 acres of TNC property, and in 2012, 5 sites were added west of TNC stocking areas in
14 the Town of Islip (Figure 62). Surveys of naturally occurring hard clam populations in Brookhaven,
15 Islip, and Babylon (2004–2012) suggest that 2011 abundance of juvenile clams in Great South Bay
16 had returned to near pre-project levels. Declines were attributed to an extensive brown tide that
17 affected the area from 2007 through 2009 (TNC 2013). However, a strong 2011 cohort sampled in
18 2012 provided some optimism for a rebound (TNC 2013) (Figure 63). Strong year-classes of juvenile
19 clams can move into larger size classes as time progresses and eventually into adulthood. The map in
20 Figure 63 shows that summer abundance of hard clams in central Great South Bay was high in 2008
21 and declined following the brown tide event. A resurgence of juveniles appeared in 2012 prior to
22 Hurricane Sandy and the occurrence of the breach, however no post-breach surveys have been
23 performed to reassess trends in this cohort.

 3 supplemented spawner sanctuaries as of October 2013 (from TNC 2013).

Seed Clam Density Across LI
2006-2014

1

2 **Figure 63.** Abundance and distribution of juvenile clams (<2.54 centimeters [1 inch] shell length) in Great
3 South Bay in 2006, 2008, 2009, 2011, and 2012 (from TNC 2013).

1 Post-breach changes in water quality have not affected the classification of seasonally certified³ or
2 uncertified shellfish lands. NYSDEC conducts intensive sampling of fecal coliform levels in
3 seasonally certified shellfish lands in Great South Bay during its triennial evaluations to ensure that
4 they meet the sanitary criteria for certification of shellfish lands during the period when they are
5 certified. The most recent triennial report includes post-breach survey data and indicated that
6 certified and seasonally certified shellfish lands are correctly classified as such; therefore no changes
7 in classification are necessary at this time (NYSDEC 2015). There may, however, be potential for
8 changing the status in the southeastern area near Narrow Bay (currently closed year round
9 uncertified) in response to post-breach declines in fecal coliform concentrations (Barnes pers. comm.
10 2016). There will be no decision on a potential status change until 2018, when the next triennial
11 evaluation will be conducted. Note that the NYSDEC surveys are only conducted during the open
12 period for the shellfish lands and not during seasonal closures; Therefore, these surveys are not
13 designed to collect data during periods when shellfish lands are closed to fishing and cannot
14 determine whether waters may have become healthy for clams since the breach during periods of the
15 year that are closed to harvest (Barnes pers. comm. 2016b). Also, NYSDEC (2015) reported that the
16 Sampling Station at Old Inlet (adjacent to the breach) was deemed inactive because it was
17 unnavigable at the time the report was written.

18 **Data Gaps**

19 Limited fishery-independent data are available to describe the bay-wide population status of hard
20 clams. Surveys for this species require specialized equipment, significant time and manpower, and
21 financial resources. The lack of such data has prevented a spatially synoptic, temporally resolved
22 understanding of hard clam population dynamics in Great South Bay. The short time period that has
23 passed since the formation of the breach limits our ability to draw conclusions regarding the dynamic
24 long-term effects of the breach on hard clams.

25 Larval distribution patterns are affected by hydrodynamics. Given that the hydrodynamics of the bay
26 have changed since the formation of the breach (refer to the “Physical Resources” section), hard clam
27 dispersal patterns may have also changed; however, there are no data available to address this.

28 Understanding the dispersal patterns of hard clam larvae is essential for understanding the population
29 dynamics for this species. A paucity of wind data has prevented a robust integration of hydrodynamic
30 models with larval dispersal models. Wind influences current patterns, which in turn have a direct
31 effect on the distribution of hard clam larval settlers. Larval clams transition through multiple phases
32 prior to settling on the ocean floor. During the veliger larval phase, larvae are carried by currents
33 throughout the water body until the clam metamorphoses to the pediveliger (pre-settlement) and
34 eventually juvenile (settlement) stage. This veliger phase can last 6–14 days (Loosanoff and Davis
35 1949) and has the potential to carry larvae over large distances.

36 **Summary of Changes since the Formation of the Breach**

³ Seasonally certified and uncertified are designations assigned to shellfish lands by the NYSDEC. Hard clams may be taken only from areas designated as certified (or open) for the harvest of hard clams.

1 The formation of the wilderness breach has had positive and negative effects on hard clams
2 depending on the region of the bay where they are located. In Bellport Bay, Narrow Bay, and
3 Western Moriches, water quality has improved. In these areas, the export of water to the open ocean
4 has ameliorated the effects of brown tide, moderated summer temperatures, and improved the quality
5 and quantity of food resources for hard clams. These changes in Bellport Bay since the formation of
6 the breach have coincided with improvements in indicators of clam success, namely growth rate and
7 CI. In Central Great South Bay, circulation patterns have changed since the breach and may now
8 create conditions that further favor brown tide blooms and negatively affect clams. In the immediate
9 location of the breach, food resources are reported to be less abundant and of lower quality, and
10 predation is reported to be greater.

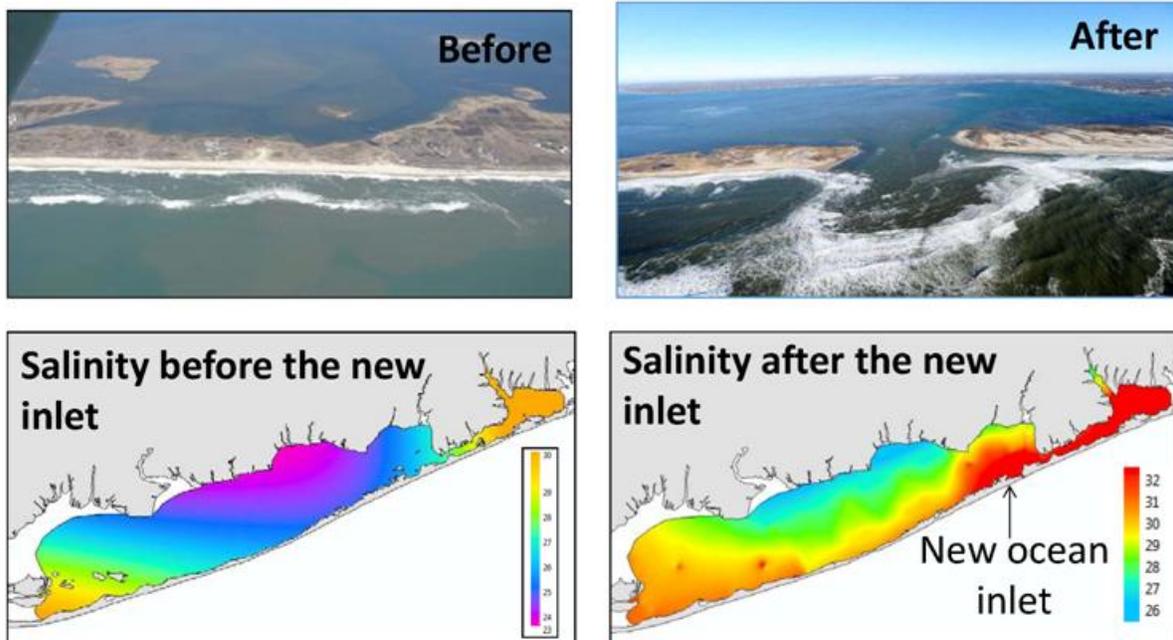

11

1 **Finfish and Decapod Crustaceans**

2 Great South Bay is a shallow, well-mixed lagoonal ecosystem that supports numerous finfish and
3 decapod crustacean species (Briggs and O’Conner 1971). Changes in the abundance and distribution
4 of salt water species in Great South Bay have occurred since the breach formed, particularly in the
5 areas of the bay affected by the influx of ocean water. These changes are evident from comparisons
6 made between faunal surveys conducted in the decade prior to the breach and surveys conducted
7 after the breach formed. This section provides a synthesis of available pre- and post-breach data on
8 the finfish and decapod crustacean communities in Great South Bay.

9 **Synthesis of Finfish and Decapod Crustacean Information and Comparison of Pre**
10 **versus Post Breach**

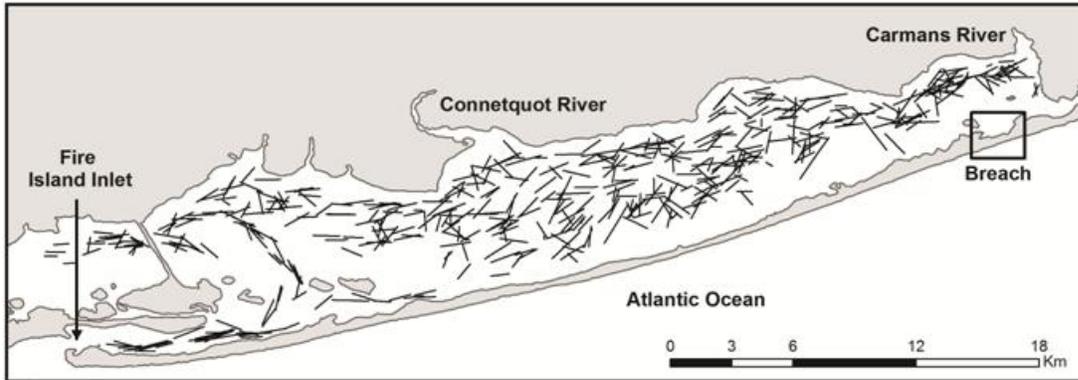

11 Great South Bay has experienced an increase in biodiversity (i.e., number of species) and in marine
12 species since the breach formed. These ecological changes are suspected in namely Bellport Bay,
13 Narrow Bay, and western Moriches Bay (Gobler, Collier, and Lonsdale 2014) where water
14 temperature has reportedly decreased and salinity has increased due to an influx of ocean water
15 (Figure 64). (It should be noted that data analyses conducted by SoMAS indicate that the impact of
16 the breach on water temperature is inconclusive (Flagg pers. comm. 2015; refer to the “Physical
17 Resources” section).

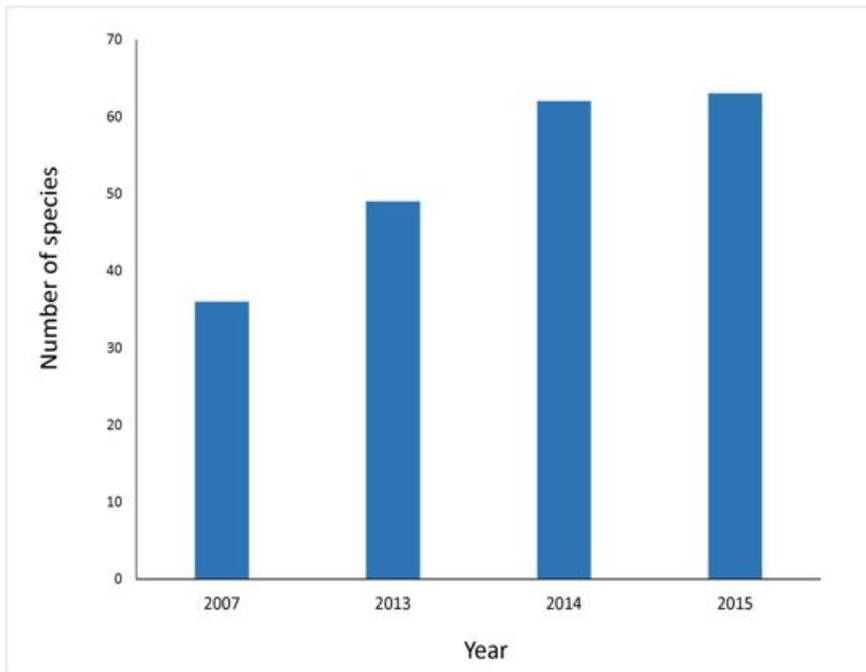

18
19 **Figure 64.** Map of salinity before the breach (left panel) and after the breach (right panel) (from Gobler,
20 Collier, and Lonsdale 2014).

21 Frisk et al. (2015) compared 2007 (pre-breach) with 2013–2015 (post breach) fish trawling data from
22 45 random stations in Great South Bay (Figure 65). Overall, there was an increase in species richness

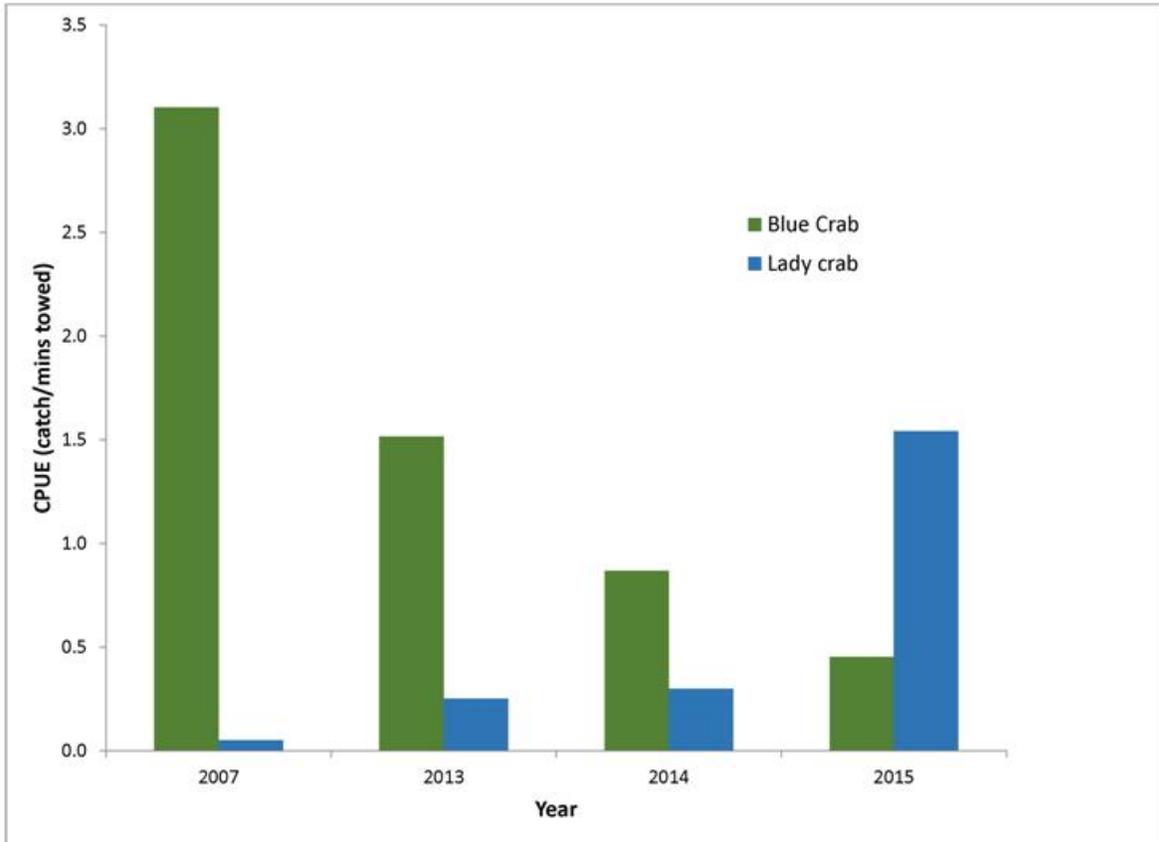

1 from 35 to 60 species and a change in species composition after the breach formed (Figure 66). The
2 study also documented an 80% decline in blue crab populations, an estuarine species, and a 500%
3 increase in lady crab populations, a species adapted to marine environmental conditions (Figure 67).
4 Similarly, squid catch per unit effort (CPUE) increased >300% after the breach, and butterflyfish
5 populations increased >100%. Bay anchovy (*Anchoa mitchilli*) also increased in relative abundance
6 (percentage of total CPUE over time) from 18% in 2007 to 79% (2013), to 62% (2014), and to 72%
7 in 2015. Although these studies are informative, it is not known whether these changes in catch size
8 are associated with the breach.

9
10 **Figure 65.** Location of trawl samples. Forty-five random samples were collected before and after the
11 breach (from Frisk et al. 2015).

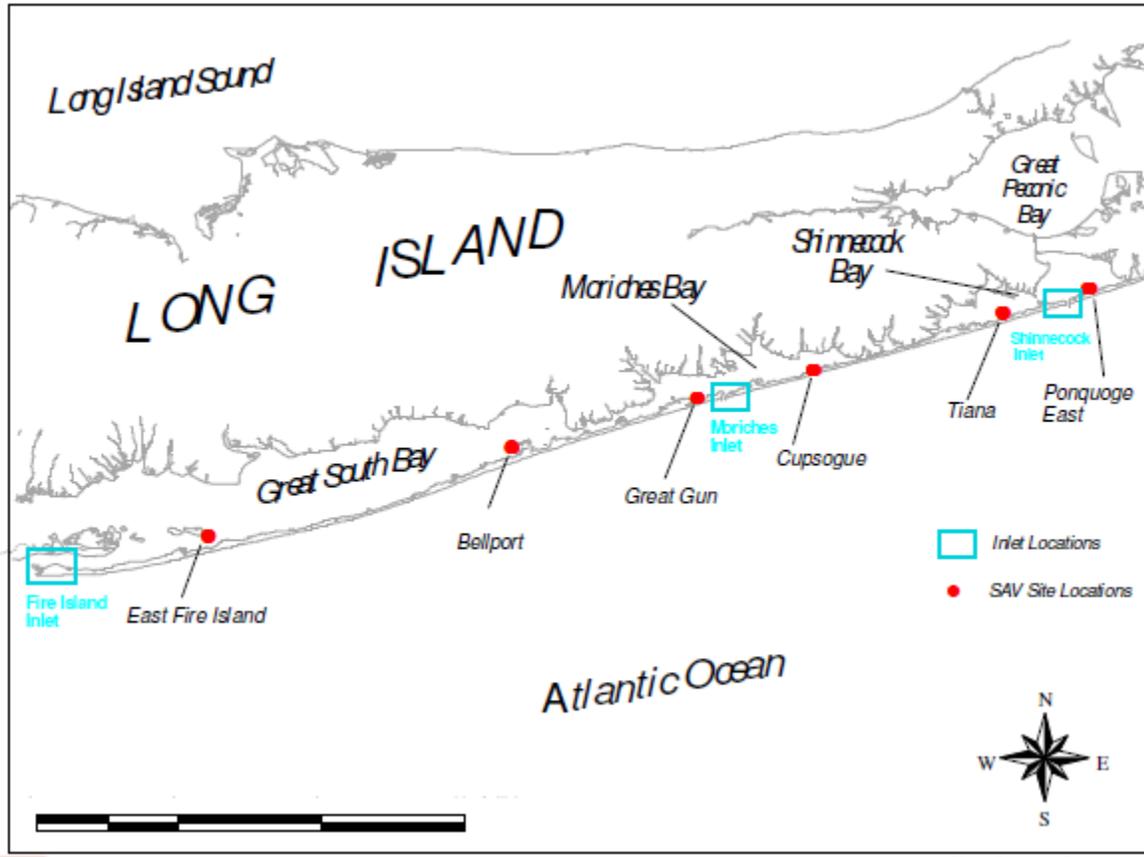

12
13 **Figure 66.** Number of species per year collected in a Great South Bay trawl survey (from Frisk et al.
14 2015).

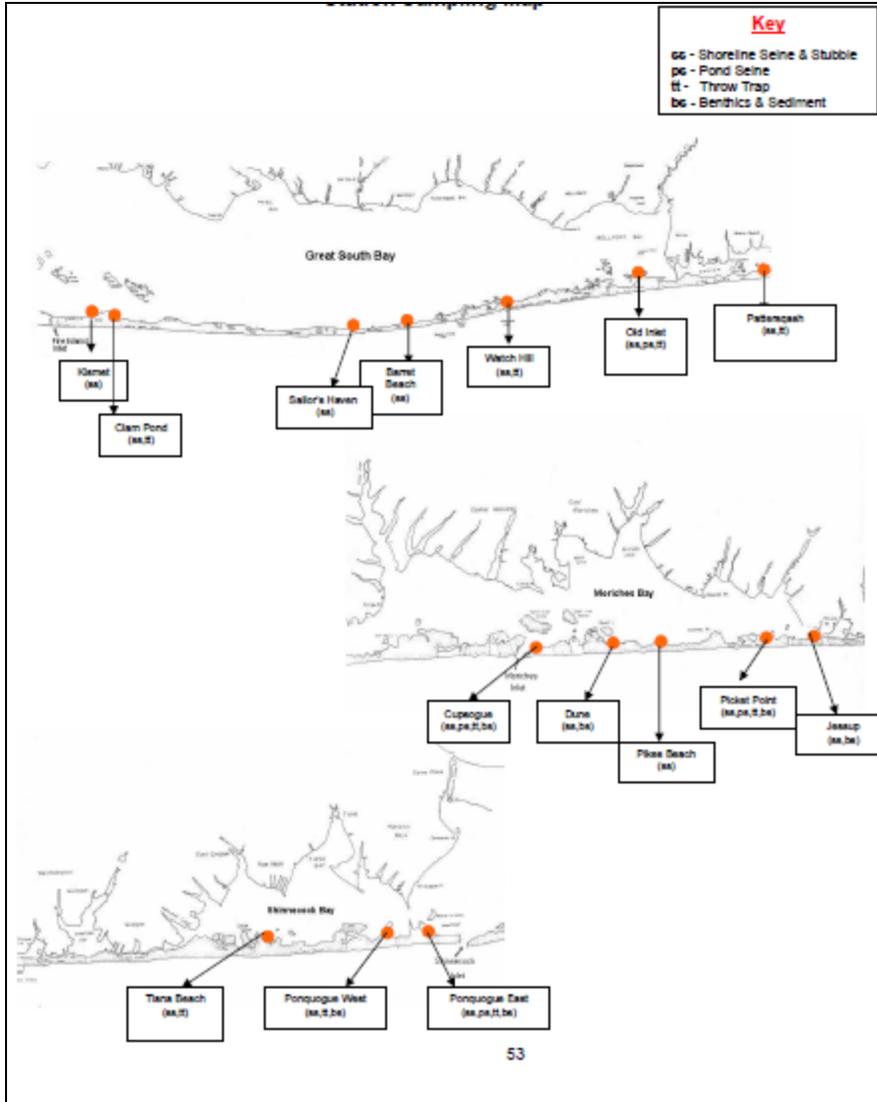

1
 2 **Figure 67.** Change in catch per unit effort over time for blue crab and lady crab collected in Great South
 3 Bay trawl survey (from Frisk et al. 2015).

4 Finfish abundance prior to the breach was recorded at sites in Great South Bay, Moriches Bay, and
 5 Shinnecock Bay (Figures 68–69). These faunal surveys indicated that both finfish abundance and
 6 diversity were lowest in Great South Bay compared to Moriches Bay and Shinnecock Bay (USACE
 7 2004b, 2006b; EEA Inc. 2002). USACE (2004b, 2006b) performed surveys of fish and invertebrate
 8 populations at 6 sites (selected specifically to assess fish populations in SAV beds) distributed evenly
 9 among Great South Bay, Moriches Bay, and Shinnecock Bay in 2003 and again in 2005. The study
 10 collected water quality data, characterized SAV habitat, and collected bimonthly samples from June
 11 to October 2003, and monthly samples from June to November 2005. Similar seining methods were
 12 used in each year, and the 2003 survey additionally employed visual observations by a snorkeler to
 13 identify any species that were not collected in the seine net. Results from the survey showed similar
 14 faunal distribution patterns in both years of the study, with both finfish abundance and species
 15 richness being lowest in Great South Bay, and increasing from west to east. The largest values
 16 reported at two sites near Shinnecock Inlet (Figures 70–73). The low finfish abundance and species
 17 richness observed in Great South Bay was attributed by the authors to greater habitat degradation in
 18 that location. In the 2003 samples, the numerically dominant fish species included fourspine
 19 stickleback (*Apeltes quadracus*) (32%), Atlantic silverside (*Menidia menidia*) (16%), and blackfish
 20 (*Tautoga onitis*) (15%). In 2005, Atlantic silversides (*M. menidia*) (26%), bay anchovy (*A. mitchilli*)

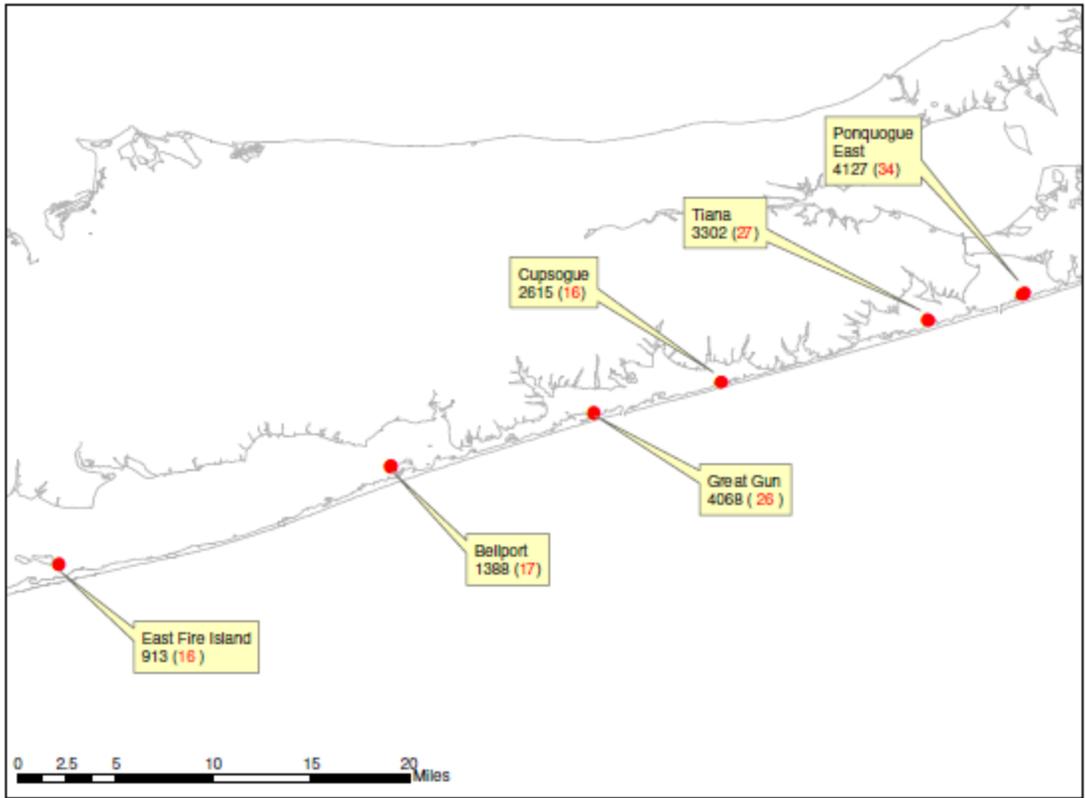

1 (16.5%), and Atlantic tomcod (*Microgadus tomcod*) (13.9%) dominated the catch. Seasonal trends
2 for abundance and species richness followed expected patterns for both years, with lower values in
3 the early spring and a peak in the late summer early fall. This reflected an influx of fish into the bay
4 as rising temperatures warm bay waters.

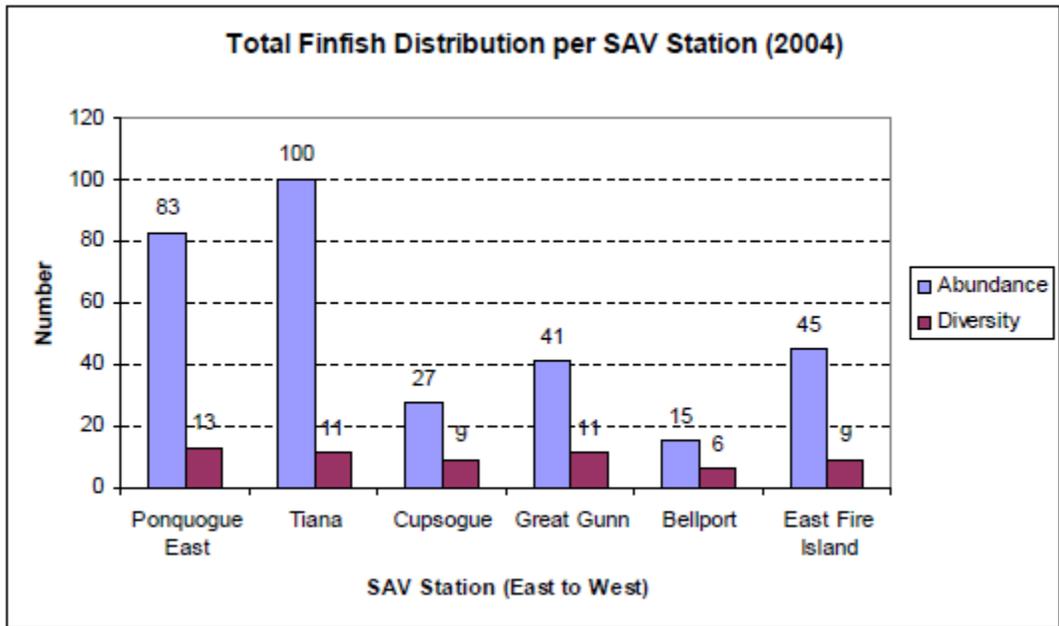

5
6 **Figure 68.** Site sampled during fish and invertebrate seine survey in 2003 (from USACE 2004b).

2 **Figure 72.** Finfish abundance per site in seine samples collected in submerged aquatic vegetation beds
 3 in 2005 (from USACE 2006b).

1
 2 **Figure 73.** Finfish diversity per site from the 2005 seine survey in submerged aquatic vegetation beds
 3 (from USACE 2006b).

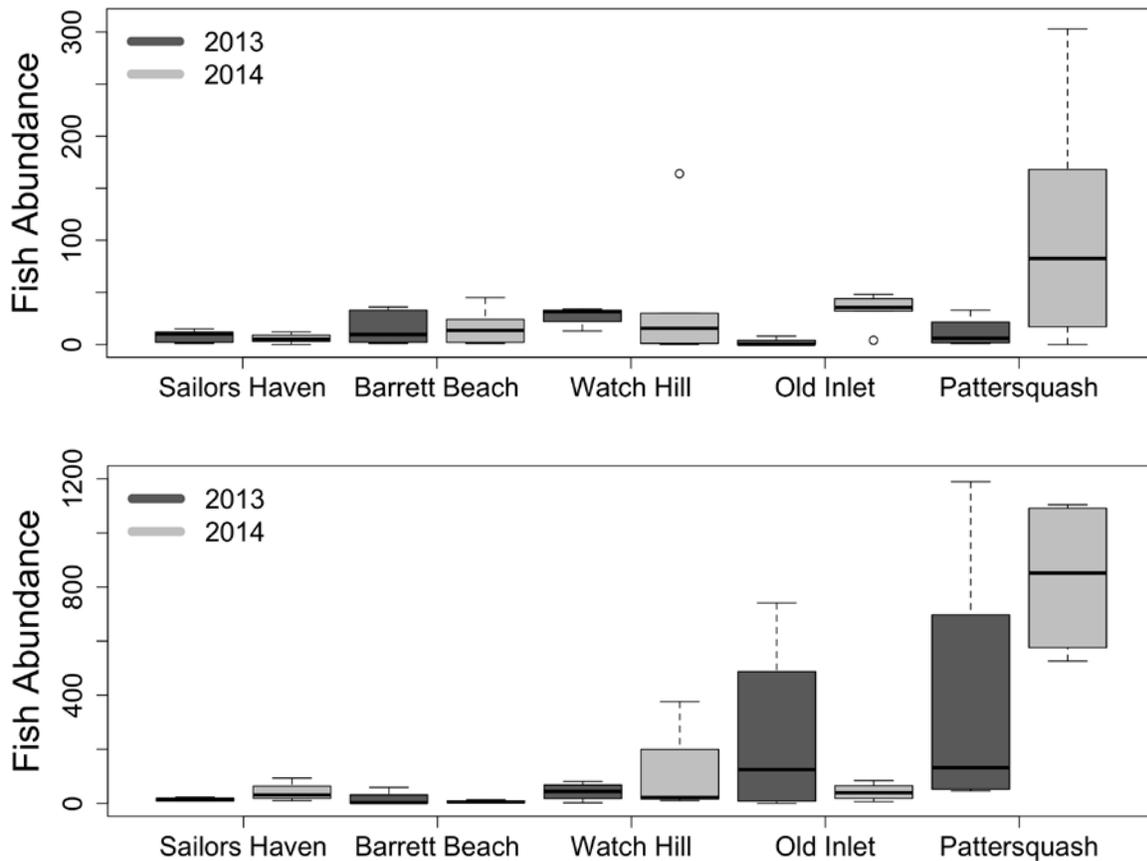

4 EEA Inc. (2002) studied fish and invertebrate populations in the region from June to October 2000
 5 and April to May 2001. Shoreline seine surveys were conducted biweekly at 15 sites from Fire Island
 6 Inlet in the west to Shinnecock Inlet in the east (Figure 69). Of these, 7 sites were located in Great
 7 South Bay, 5 sites were located in Moriches Bay, and 3 sites were located in Shinnecock Bay.
 8 Additionally, a throw trap survey was conducted at a subset of 9 of these sites in September 2000, in
 9 which fish were sampled with a dip net during the evaluation of the SAV in the throw trap.
 10 Additionally, 4 tidal ponds were surveyed with a seine in September 2000. Similar to the geographic
 11 trends reported by the USACE studies (2004b, 2006b), the EEA Inc. (2002) shoreline seine survey
 12 found that Great South Bay had the lowest abundances of fish overall, and that in general, finfish
 13 abundance increased from west (Great South Bay) to the east (Shinnecock Bay) (Figure 74). Similar
 14 geographic patterns were observed in the tidal pond survey. Abundance and diversity of finfish in the
 15 shoreline seine peaked in the late summer and early fall with numerical dominants including Atlantic
 16 silversides (*M. menidia*), sand lance (*Ammodytes*), striped killifish (*Fundulus majalis*), bay anchovy
 17 (*A. mitchilli*), and spotfin killifish (*Fundulus luciae*). Fish densities in the throw traps were generally
 18 low and of similar composition to the shoreline seines. Mummichog (*Fundulus heteroclitus*) and
 19 sheepshead minnow (*Cyprinodon variegatus*) dominated catch in the four tidal ponds that were
 20 sampled.

1
 2 **Figure 74.** Finfish species richness (top panel) and finfish abundance (bottom panel) at each site during
 3 seine survey conducted in 2000–2001 (from EEA Inc. 2002).

4 After the breach formed, the relative abundance of fish near and east of the breach increased
 5 compared to other sites in the survey (Peterson 2015a, b). Peterson (2015a, b) found that sites near
 6 Old Inlet and at Pattersquash in Moriches Bay had higher finfish abundance compared to three other
 7 sites ranging geographically from Great South Bay to Moriches Bay (Figure 75). The most common
 8 species in the survey included bay anchovy, Atlantic silverside, and three-spine stickleback. In
 9 seines, the dominant species were bay anchovy, Atlantic silverside, and killifish; and Atlantic
 10 silversides and pipefish (*Syngnathinae*) dominated throw trap samples. Atlantic silverside density
 11 contributed to the higher abundance values observed at both Old Inlet and Pattersquash, and the
 12 decline from 2013 to 2014 in seine abundance noted at Old Inlet reflected a decrease in Atlantic
 13 silverside abundance at that site.

14

1

2

3 **Figure 75.** Fish abundance from seine surveys (top panel) and trawl surveys (bottom panel) conducted in
 4 2013 and 2014 (from Peterson 2015a).

5 A comparison of pre-breach versus post-breach abundance for migratory finfish was made between
 6 data from long term surveys performed before and after the 2012 breach. The studies were performed
 7 downstream of the dam in the tidal portion of the Carmans River, which empties into Bellport Bay,
 8 and which may provide habitat for some life stages of migratory finfish. Long-term monitoring data
 9 suggests that the anadromous alewife (*Alosa pseudoharengus*) migration run returns to the Carmans
 10 River have increased since the breach formed, a possible indicator that alewife are entering Great
 11 South Bay through the breach (Frisk pers. comm. 2016). Since 2000, the NYSDEC has been
 12 conducting an annual survey of American eel (*Anguilla rostrata*) abundance in the Carmans River
 13 (NYSDEC 2015b), by deploying a fyke net for a six-week period in early spring. Glass eel
 14 abundance, the early juvenile phase of the catadromous American eel, was notably higher during
 15 2012 and 2013 when compared to abundance data from the previous nine years. However, glass eel
 16 abundance subsequently declined in 2014 and 2015 survey samples. Although increased numbers of
 17 glass eels during the 2013 survey could be associated with conditions caused by the breach, similarly
 18 high numbers were recorded in the spring 2012 survey which pre-dated the breach. It is possible that

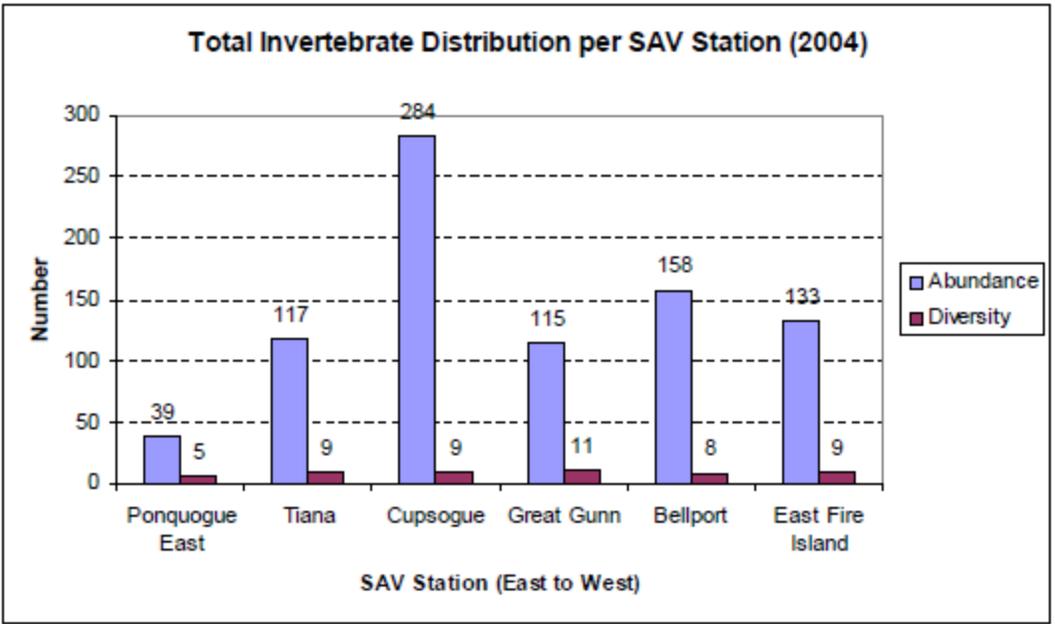

1 some other factor contributed to the observed patterns in glass eel abundance for the American eel
2 species. Therefore, it is unclear whether the breach affected glass eel abundance at Carmans River.

3 Habitat for freshwater and brackish water species has declined since the breach formed. This is
4 demonstrated by pre- and post-breach trawl surveys conducted by Frisk et al. (2015) which showed a
5 sharp post-breach decline (80%) in blue crab abundance after the breach formed (Figure 67). As an
6 estuarine species, blue crab are adapted to the reduced salinity levels that occur within estuary
7 habitats and are less tolerant of ocean water salinity levels; therefore, it is possible that blue crab
8 populations have retreated closer inland to habitat with lower salinity levels (such as brackish water
9 found in tributaries), but no data are yet available to support this idea (McKown pers. comm. 2016).

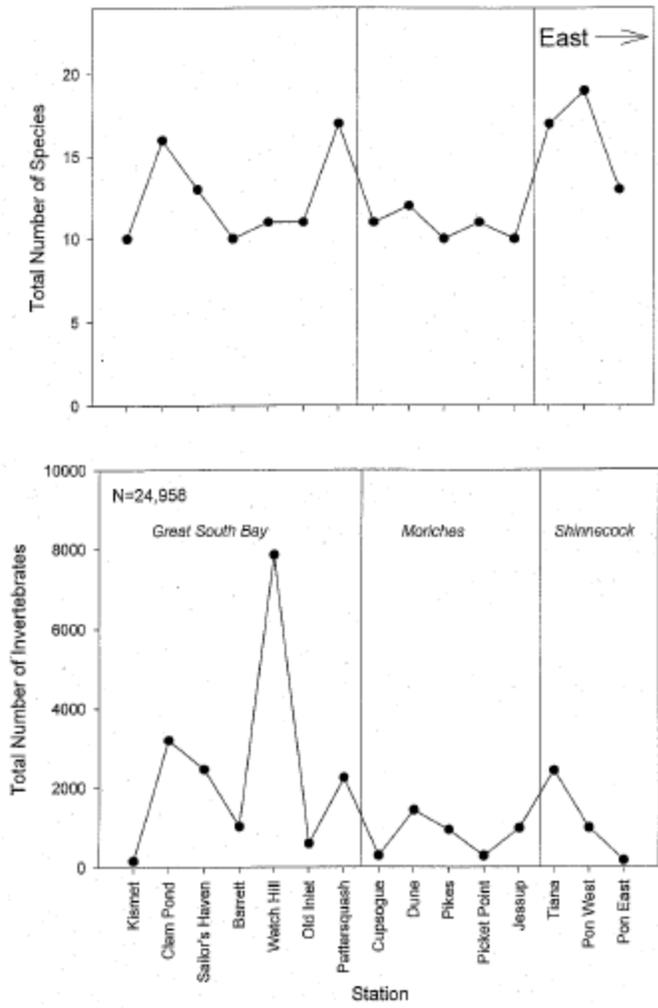

10 Return of SAV is providing habitat for finfish and invertebrates since the breach formed. Prior to the
11 breach, *Ruppia* had dominated seagrass beds in Great South Bay, and eelgrass which provides high
12 quality nursery habitat and refugia from predators for fish (Raposa and Oviatt 2000), had undergone
13 a significant decline (Peterson 2015a, b; see the “Submerged Aquatic Vegetation” section). *Ruppia*,
14 while providing some fish habitat, is a shorter grass with less physical complexity, and offers lower
15 habitat value overall (Peterson 2015a, b). Since the breach formed, the clearer, cooler water resulting
16 from the open exchange of ocean water into Great South Bay has promoted the rapid recovery of
17 eelgrass beds (see the “Submerged Aquatic Vegetation” section) particularly in areas adjacent to the
18 breach and to the east towards Moriches Inlet (Peterson pers. comm. 2015a, b). These new beds of
19 SAV are providing habitat for fish. Peterson (2015a, b) monitored fish abundance in beds of eelgrass
20 and *Ruppia* from 2013 to 2014. Abundance increased between survey years and higher densities of
21 juvenile summer flounder and tropical species (with higher salinity level tolerance) were observed in
22 eelgrass beds adjacent to the breach. Previous studies have similarly found strong associations with
23 SAV characteristics such as shoot height or density and finfish abundance (Raposa and Oviatt 2000;
24 Briggs and O’Conner 1971; and USFWS 1981, but see USACE 2006b).

25 *Spartina* beds also provide habitat for fish and invertebrates. Prior to the breach, EEA Inc. (2002)
26 documented increasing invertebrate abundance coinciding with *Spartina* biomass in all bays, and
27 with finfish abundance in Great South Bay; however, these trends were not statistically significant.

28 Invertebrates may experience high predation by finfish near the breach. Pre-breach studies
29 demonstrated an inverse relationship between finfish and invertebrate abundance at certain locations.
30 For example, invertebrates were found to have greatest abundance where fish abundance was lowest
31 in a 2004 survey reported by USACE (2006b) (marsh grass shrimp [*Palaemonetes vulgaris*] and
32 green crab [*Carcinus maenas*] in Cupsogue, Moriches Bay) and in a 2000–2001 survey conducted by
33 EEA Inc. (2002) (marsh grass shrimp [*P. vulgaris*]; sand shrimp [*Crangon septemspinosa*]; and blue
34 crab [*Callinectes sapidus*] in Great South Bay) (Figures 71, 74, 76, 77). This is likely a result of
35 reduced predation due to lower fish abundance. After the breach formed, Peterson (2015a, b)
36 observed lower grass shrimp densities near the wilderness breach where he also observed higher fish
37 densities, which he hypothesized could be driving down shrimp abundance. Predation also affects
38 seasonal trends in invertebrate abundance. For example, EEA Inc. (2002) found that invertebrates
39 were most abundant in the summer, with the exception of an August low, which the authors
40 attributed to predation by fishes which peaked in abundance during this month.

1
 2 **Figure 76.** Invertebrate abundance and diversity in seine samples collected in submerged aquatic
 3 vegetation beds during 2004 survey (from USACE 2006b).

1
 2 **Figure 77.** Invertebrate species richness (top panel) and abundance (bottom panel) from seine survey
 3 conducted in 2000–2001 (from EEA Inc. 2002).

4 **Data Gaps**

5 Patterns of change in the finfish and decapod crustacean community since the breach formed are just
 6 beginning to emerge. There has been little elaboration on how these changes may affect ecosystem
 7 function or how burgeoning populations of species such as lady crab or squid may affect the overall
 8 ecology of Great South Bay, although such efforts are planned (Frisk et al. 2015). Increased energy
 9 exchange with the open ocean could have important implications for finfish and decapod
 10 communities. Since the breach occurred in 2012, considerable work has been done to evaluate the
 11 potential implications of the breach. However, additional data and studies are needed to continue to
 12 evaluate and address questions related to response of finfish and decapods to the breach, and to
 13 develop and publish results of the research data in scientific journals. As such, it is too early to
 14 determine or predict potential long-term effects of the breach on the Great South Bay finfish and
 15 decapod communities.

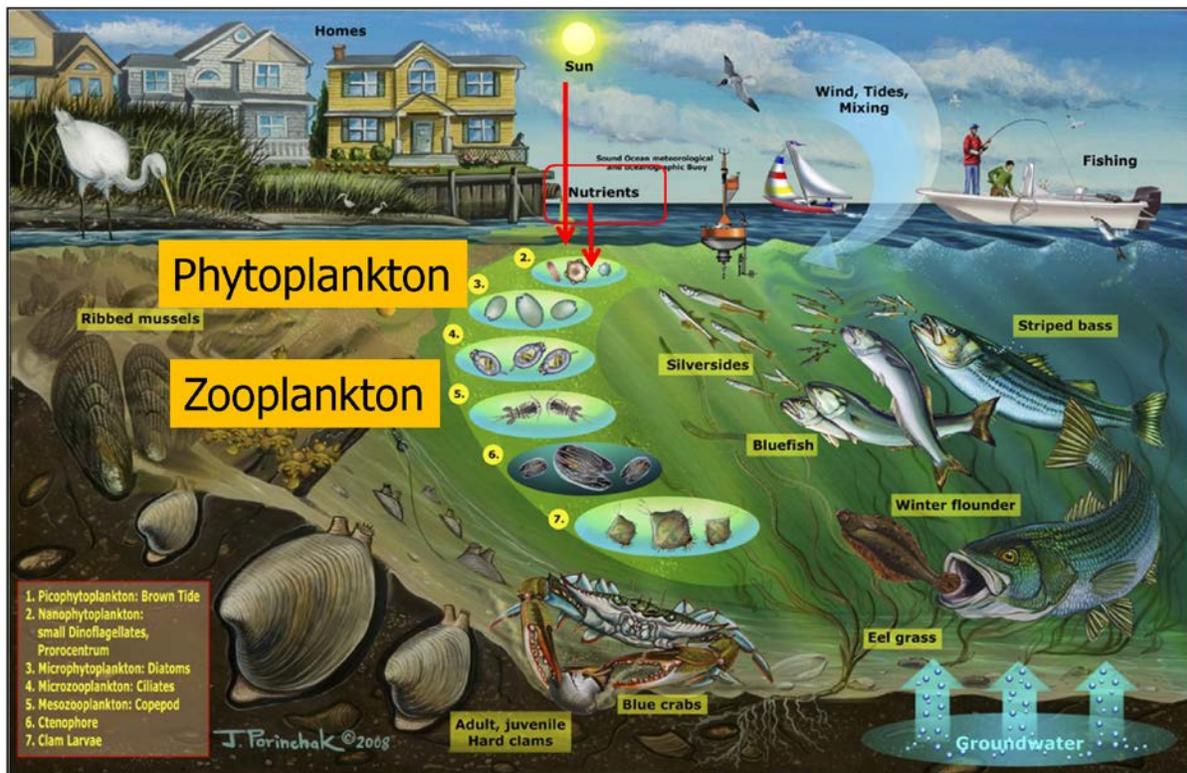

16 **Summary of Changes since the Formation of the Breach**

1 The formation of the breach resulted in increased exchange of saltwater, organisms, and energy
2 between the open ocean and Great South Bay, resulting in increased species richness. In addition,
3 abundance of some species has decreased, while other species have shown an increase in abundance,
4 a trend that has been attributed to improvements in water quality, moderated water temperatures, and
5 greater habitat availability (i.e., increased SAV density and eelgrass). Decreased abundance for some
6 species is likely a result of increased predation from increasing populations of associated predators or
7 to changes in their environment (e.g., temperature and salinity).

8

1 Ecosystem Structure and Processes

2 An ecosystem is an integration of an ecological community with its environment, and the health of an
3 ecosystem can be described as “a comprehensive, multiscale, dynamic, hierarchical measure of
4 system resilience, organization, and vigor” (Costanza 1992). This technical synthesis report
5 examined major habitat types and major faunal groups in separate sections; however, the biological
6 reality is that the Great South Bay ecosystem is a dynamic integration of all of these groups and
7 habitats interacting simultaneously. These interactions include trophic (i.e., feeding) relationships
8 among the bay’s diverse array of fauna and flora, the habitats where these interactions occur, and a
9 suite of abiotic processes that operate in the system such as nutrient cycling and decomposition. The
10 exchange of energy and nutrients among organisms that occurs through trophic relationships can be
11 conceptualized as a food web (Figure 78). A change in population size of one species, taxa, or
12 functional group, will have direct effects on groups to which it is directly linked in the food web, and
13 indirect effects on potentially many more groups through diffuse food web linkages (Paine 1966).
14 Food web-based metrics, such as the number of trophic links, amount of biomass at upper trophic
15 levels, or the level of biodiversity, can provide some insight into the maturity (Odum 1969), stability,
16 and resilience of the ecosystem to disturbance (Rooney and McCann 2012; Nuttall et al. 2011). This
17 section synthesizes the existing information on community and ecosystem level patterns and
18 considers how these patterns might be altered in response to the breach that occurred as a result of
19 Hurricane Sandy in 2012.

20

21 **Figure 78.** Food web structure of Great South Bay (from Gobler, Collier, and Lonsdale 2014).

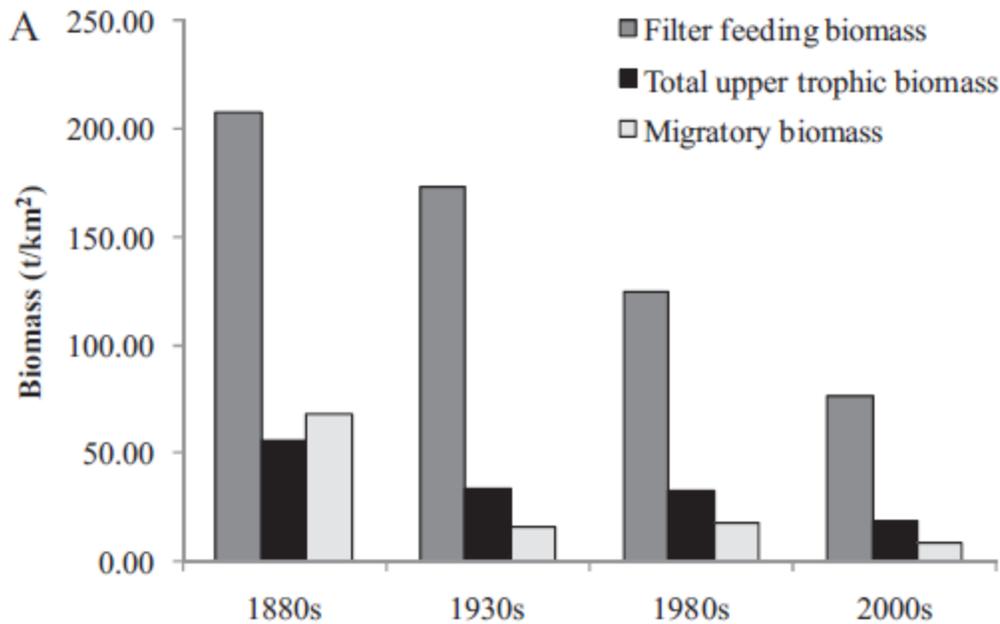

1 **Synthesis of Information: Comparison of Pre versus Post Breach**

2 Enclosed or semi-enclosed lagoons like the Great South Bay are often sensitive to natural and
3 anthropogenic stressors, which can directly affect ecological communities (Nichols and Boon 1994;
4 Spaulding 1994). Ecological patterns can be disrupted or altered by human intervention (e.g., through
5 fishery harvest or modification of natural inlets), the opening of inlets via stochastic weather events,
6 or large-scale changes in environmental regimes driven by global climate events (Cerrato, Locicero,
7 and Goodbred 2013). A combination of these factors led to dramatic ecological shifts in Great South
8 Bay even before the breach formed (Nuttall et al. 2011). The opening of the wilderness breach by
9 Hurricane Sandy created conditions in which seawater is freely exchanged between the bay and the
10 ocean, resulting in increased salinity (Figures 27–28), higher flow, more moderate temperatures
11 (cooler in summer, warmer in winter; Figures 29–30), and an increased exchange of organisms
12 (Figures 66–67) with the ocean (Gobler, Collier, and Lonsdale 2014; Cerrato and Frisk pers. comm.
13 2016). All of these changes have taken place in the context of existing human disturbance and long-
14 term historical dynamics.

15 Ecosystem maturity in Great South Bay has declined over the last 120 years (Nuttall et al. 2011).
16 Lower maturity is associated with lower total biomass, fewer upper trophic level predators, lower
17 connectivity to the ocean due to fewer migratory species, and a less complex food web exhibiting
18 fewer trophic linkages and dominance by lower trophic levels. The shift in ecosystem maturity of
19 Great South Bay has been attributed to the reduced role of rapid “state” changes such as the opening
20 of inlets by storms, which has been replaced with human practices such as engineering of permanent
21 inlets and closure of breaches (Nuttall et al. 2011). An increase in one or more of the ecosystem
22 maturity metrics could provide evidence for a recovery of ecosystem maturity in Great South Bay.
23 The formation of the breach has affected some of these metrics, with the resulting effects
24 summarized below.

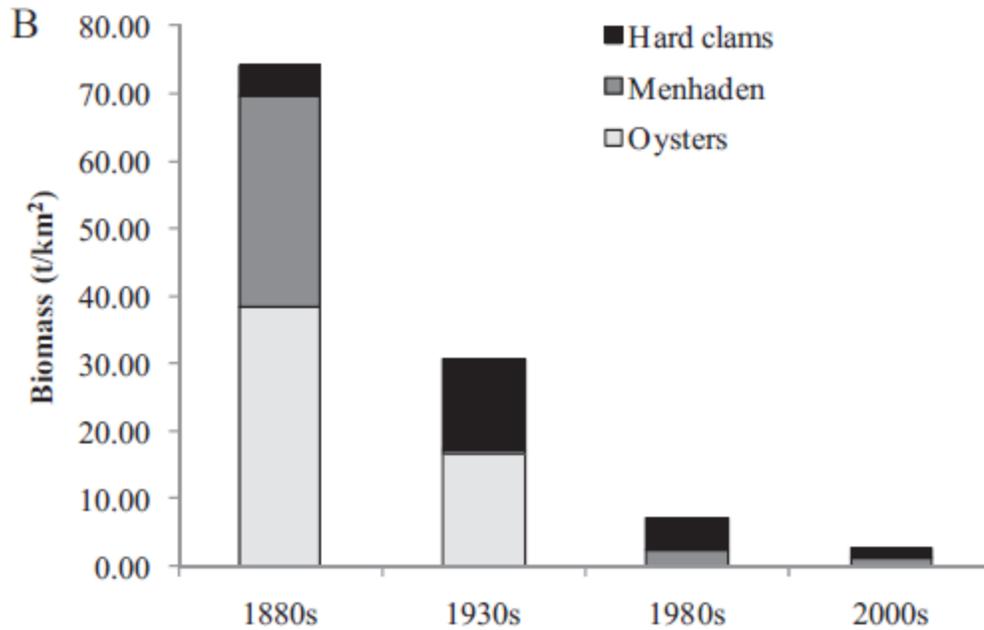

25 Prior to the breach, a shift away from the functional dominance of upper trophic level predators such
26 as sand tiger shark, weakfish, and gadoids was reported for Great South Bay, resulting in an
27 ecosystem dominated by mid-level predators (Nuttall et al. 2011) (Figure 79). The breach opening
28 provides a portal through which these species, and the smaller fish that are their primary food
29 resource, could enter the bay. Although a sand tiger shark nursery has recently been discovered in
30 Great South Bay (New York State Aquarium 2016), it is unknown whether it is associated with the
31 breach. There is insufficient information to determine or predict the potential long-term effects to the
32 trophic structure of Great South Bay resulting from the breach opening.

33 Species richness has increased in the bay since the formation of the breach (Figure 66). Frisk et al.
34 (2015) demonstrated that there are more species, more total biomass, and likely more trophic
35 linkages and a more complex food web in the bay since the breach compared to before the breach
36 formed. The authors suggest this as further evidence for a recovery of ecosystem maturity and
37 increased resilience to disturbance (Cerrato and Frisk pers. comm. 2016; Frisk et al. 2015).

1
 2 **Figure 79.** Biomass of filter feeders (i.e., suspension feeders), upper trophic levels, and migratory species
 3 has declined since the 1880s. Filter feeders included hard clams, oysters, other suspension feeders, sand
 4 shrimp, other shrimp, menhaden, and zooplankton. Migratory species included black sea bass, bluefish,
 5 gadids, menhaden, scup, sharks, skates, squid, striped bass, summer flounder, weakfish, winter flounder,
 6 and tropical fish (from Nuttall et al. 2011).

7 Suspension feeding by shellfish has been in decline since the 1880s and has been missing from the
 8 Great South Bay ecosystem for the last 30 years (Gobler, Lonsdale, and Boyer 2005; Kraeuter et al.
 9 2008) (Figure 80). Hard clams, oysters, and menhaden once performed the crucial ecosystem
 10 function of suspension feeding, which removes phytoplankton and other suspended organic matter
 11 from the water column, thereby clarifying the bay water. Active commercial fishing, changes to the
 12 environment, and predation pressure brought about by the formation of Moriches Inlet in 1931 led to
 13 the collapse of the oyster population in the early 1950s (McHugh 1972). Similarly fisheries harvest,
 14 increased juvenile predation rates, and increased frequency of brown tide have severely depleted the
 15 bay’s stock of hard clams (Gobler, Lonsdale, and Boyer et al. 2005; Bricelj 2009; McNamara,
 16 Lonsdale, and Cerrato 2010). Since the wilderness breach formed in 2012, hard clam populations in
 17 Great South Bay have continued to exhibit low densities (as indicated by fishery landings provided
 18 by Barnes pers. comm. 2016a) and severely low spawning and reproductive success (Figure 63).
 19 There are insufficient data to determine whether a natural recovery in hard clam populations and the
 20 ecosystem function of suspension feeding will result even if conditions favoring recovery occur in
 21 any part of Great South Bay, either with the breach open or with the breach closed.

1
 2 **Figure 80.** Biomass of three major suspension feeding groups has declined since the 1880s (from Nuttall
 3 et al. 2011).

4 Atlantic menhaden, a mobile suspension feeder, also once performed the vital function of suspension
 5 feeding for Great South Bay, removing detritus, phytoplankton, and zooplankton from the water
 6 column to use as food (Deegan et al. 1990; Durbin and Durbin 1998; Nuttall et al. 2011). Intense
 7 fisheries for this species led to its collapse in 1966 (McHugh 1972). However, with the breach open
 8 there is a new physical entryway through which menhaden could enter Great South Bay. Survey data
 9 for menhaden suggest that this species is present but patchily distributed in Great South Bay, but
 10 that they are not nearly as abundant as they once were historically (Frisk et al. 2015). Currently, there
 11 are insufficient data to determine whether an increase in menhaden and the ecosystem function of
 12 suspension feeding that they provide will result with the breach open.

13 The pre-breach loss of suspension feeders, namely oysters, hard clams, and menhaden, has likely
 14 contributed to greater levels of phytoplankton in Great South Bay, a shift from benthic to pelagic
 15 primary production, and potentially a shift in the types of phytoplankton in the ecosystem (Figures
 16 34–40). Low water clarity and light attenuation at the bay bottom prevents the growth and expansion
 17 of seagrass beds that can provide habitat for finfish and invertebrates (e.g., Peterson 2015a, b).
 18 However, despite the absence of a dominant suspension feeder, post-breach water clarity has
 19 improved in the Bellport Bay, Narrow Bay, and western Moriches Bay areas (Gobler pers. comm.
 20 2015) due to the export of suspended matter out to the ocean through the breach (Figure 41). This,
 21 together with the reportedly cool, saline water that the breach is bringing into the bay, has been
 22 linked to improved conditions for eelgrass (Figures 49–50) (Peterson 2015a; Heck and Peterson
 23 2016).

1 Shifts in species composition in the areas affected by the breach have been reported; however the
2 long term impact on these shifts on ecosystem function is not yet understood. For example, there has
3 been a notable decline in blue crab and a subsequent increase in lady crab since the breach formed
4 (Figure 67) (Frisk et al. 2015). It is not known whether this shift in species composition is related to
5 the breach. However, both species are scavengers commonly feeding on mollusks and crustaceans.
6 Total predation by crabs may increase if the post-breach density of lady crab exceeds the pre-breach
7 density of blue crabs. Moreover, McKown (pers. comm. 2016) suggested the potential for a spatial
8 shift in blue crab distribution, with blue crabs moving into the lower salinity tributaries to escape the
9 higher salinities in the areas affected by the breach.

10 Habitats such as eelgrass, marshland, and the sediments on the bay bottom provide unique spatial
11 resources for particular taxonomic groups. For example, eelgrass beds and other SAV provide
12 nursery and refugia habitat for crustaceans and juvenile fishes (McElroy et al. 2009 and citations
13 therein). Marshes provide habitat for shellfish and foraging habitat for shorebirds, and sand and mud
14 sediments support unique benthic communities (Cerrato, Locicero, and Goodbred 2013). In addition
15 to the potential for expansion of eelgrass, there is also potential for new marsh habitat to develop in
16 newly formed flood tide deltas (Figure 42) and overwash areas that provide platforms on which
17 marsh vegetation is likely to become established, given appropriate elevation and available
18 propagules. These new flood tide deltas have the potential to support new marshes, which has
19 occurred historically in other overwash areas throughout Great South Bay.

20 Paleo-ecological data for central Great South Bay has demonstrated a shift in the last ~650 years
21 from coarse sediments to organically rich muddy sediments, and appears to favor a shift toward
22 assemblages dominated by the dwarf surf clam (*Mulinia lateralis*) (Cerrato, Locicero, and
23 Goodbred 2013). The authors attribute this shift to global climate shifts affecting storm frequency as
24 well as human land use, both of which affected sediment deposition in the central Great South Bay
25 (Cerrato, Locicero, and Goodbred 2013). The dwarf surf clam assemblage is associated with
26 environmental disturbances; therefore, the increasing dominance of dwarf surf clam dominated
27 assemblages over the last 300 years suggests that the Great South Bay has experienced increasing
28 levels of environmental disturbance in that period (Cerrato, Locicero, and Goodbred 2013). The
29 authors suggest that engineering projects to stabilize inlets or nourish beaches would make it more
30 likely that the deposition and expansion of muddy sediments will continue, which could make the
31 ecosystem more susceptible to disturbance and limit the recovery of recent species that depend upon
32 coarser sand sediments for habitat (Cerrato, Locicero, and Goodbred 2013). This work suggests that
33 engineering or dredging to stabilize the breach could further increase the susceptibility of Great
34 South Bay to disturbance.

35 **Data Gaps**

36 The Great South Bay ecosystem has historically experienced many forms of directional, human-
37 induced impacts as well as stochastic weather and climate events. The effects of the wilderness
38 breach that formed during Hurricane Sandy in 2012 is just beginning to be quantified and
39 understood. Little information is available, from either before or after the breach, to describe some of
40 the ecosystem level processes such as nutrient cycling, decomposition, and biomass turnover rates.

1 **Summary of Changes since the Formation of the Breach**

2 Ecosystem maturity of Great South Bay has increased since the formation of the breach. This
3 includes increased biomass and species diversity, greater connectivity to the ocean, and development
4 of a more complex food web with more trophic links. More mature ecosystems are healthier, more
5 stable, and more resilient to disturbance. Although post-breach improvement in some metrics of
6 ecosystem maturity and ecosystem health are expected or have already occurred, it is not known
7 whether other remaining ecosystem functions will recover, such as consumption by upper trophic
8 levels or suspension feeding and its impact on water clarity. The formation of the breach has
9 contributed to the expansion of eelgrass beds, which in turn have been associated with increased fish
10 and invertebrate production. There is potential for marsh habitat expansion on the developing flood
11 tide deltas as well, which could likewise provide new habitats for floral and faunal species.

Appendix A: Benthic Community Recovery

Benthic communities are generally thought to recover quickly following a disturbance. However a number of factors influence the rate of recovery, including definitions of “recovery,” and methods used to measure it. The purpose is to provide information on benthic recovery from the literature that may inform the general discussion of potential benthic changes in the vicinity of the wilderness breach. The following subjects are covered: (1) general principles of succession and benthic recovery; (2) factors affecting benthic recovery rates; (3) study methods for determining benthic change or recovery; (4) recovery rate estimates from the literature.

1. Benthic Community Recovery: General Principles

Benthic community recovery can be described using general benthic succession paradigm (Pearson and Rosenberg 1978; Rhoads and Germano 1986) that describes changes to the community following disturbance as a three-stage process. Pioneering (Stage I) organisms, such as tube-dwelling polychaetes and small bivalves quickly colonize the surficial sediments. These opportunistic taxa usually occur in high abundance and low species diversity. Over time they are replaced by larger, longer-lived and deeper burrowing (Stage II) organisms. With more time, Stage III benthic assemblage develops, and is characterized by a more diverse but less abundant group of larger taxa with more physical structure and functional groups.

While recovery may follow this general trend, and the early literature provides a basis on which to evaluate specific benthic community studies, a number of factors affect the nature of progression and rate of change in the benthos in any given situation.

2. Factors Affecting the Nature and Timing of Recovery

Variables known to affect recovery rates include sediment grain size and organic matter, spatial scale of disturbance, timing and frequency of disturbance, latitude, physical parameters such as slope and stability of affected sediments, and the life history of resident species (Kotta et al. 2009; Wilber and Clarke 2007; Newell et al. 1998), and the availability and transport of larval sources (Todd 1998). In addition, divergent reassembling can occur late in the benthic recovery process, making the prediction of community structure difficult (Van Colen et al. 2010).

3. Evaluating Change in Benthic Communities

Measuring changes in benthic communities can be difficult because of the natural variability inherent in most benthic systems. Looking for these changes is generally done by comparing a disturbed or new benthic community to a pre-disturbance baseline condition, a reference community, or both. Comparison to both is done using a “before-after-control-impact” study design. With any one of these approaches, data analysis methods matter, and these methodological factors influence study conclusions just as much as the physical factors that influence recovery (Wilber and Clarke 2007). Benthic communities are often compared using univariate methods such as total abundance, taxa richness, and total biomass. These parameters are useful descriptors but do not provide a complete analysis of whether a recovery has occurred. Diversity indices are sometimes used to reduce multivariate data (e.g., abundance of multiple species) into a single index such as the Shannon-Weiner diversity index (H'), or Pielou’s evenness index (J'). Changes between sites or over time are

1 plotted as means and confidence intervals for each site and time, and ‘recovery’ can be identified
2 when values for an impact area are no longer significantly different from a reference or baseline
3 condition. Similarly, if pre- and post-breach data were available, a change from a pre-breach to post-
4 breach condition could be identified when values for the new condition are significantly different
5 from those for the baseline. Multivariate analyses are also useful. Cluster analysis, which provides
6 dendograms that group samples so that samples within a group are more similar to each other than
7 samples from different groups. By defining these different groups for a set of samples, distinct
8 differences between the communities from a set of samples or stations can be described. Comparison
9 of breach area benthos to those in areas outside the influence of the breach could be done using this
10 method. Another method includes non-parametric multi-dimensional scaling ordination plots using
11 the Bray-Curtis similarity measure to identify groups of samples having similar (or different) faunal
12 assemblages. One last method for determining change in benthic communities is to define a baseline
13 or expected range for some parameter such as diversity, determine a threshold value beyond which it
14 is not expected to change as a result of ‘normal’ variation, and evaluate whether the measure
15 approaches that threshold (Keay and Mickelson 2000). All of these methods require a large number
16 of samples because of the natural patchiness and variability in the benthic community. In short,
17 measuring change or recovery in benthic communities is complex, and teasing out the effects of the
18 breach from natural variability will be challenging particularly given the lack of pre-breach data.

19 **4. Recovery Times following Disturbance**

20 Benthic communities appear to recover (or return to a condition indistinguishable from baseline or
21 reference conditions) within months to a few years. Newell et al. (1998) characterized typical
22 recovery times at 6–9 months for mud habitats and 2–3 years for sand and gravel. Kotta and others
23 (2009) found recovery to be complete after one year following a major dredging project.

24 Wilber and Clarke (2007) summarized the results of more than 60 studies on benthic recovery time
25 following dredging, filling, or capping, and showed that most systems recovered within a year,
26 although a few of the studies reported recovery times as long as 3–4 years. The authors concluded
27 that, although recovery rates are difficult to predict, suites of factors can be associated with either
28 recovery measured in months (such as shallow, naturally disturbed habitats, unconsolidated, fine
29 grain sediments, analyzed with univariate analytical approaches), or years (deep, stable habitats, sand
30 and gravel sediments, and multivariate or functional group analytic techniques). Further, the most
31 consistent physical parameter influencing recovery rates is the prior disturbance history of the site in
32 question. The breach area can be characterized as sandy and shallow, previously stable but now
33 changing to a more dynamic environment with higher flow. Benthic community recolonization, and
34 development of a new, higher-salt community on new overwash and intertidal areas, is likely to have
35 occurred since the breach. Additional field study would be useful in comparing the near-breach
36 benthic system to a reference area.
